These fMRI studies consistently reported that two cortical areas respond during movement observation, execution, and imitation: the anterior intraparietal sulcus (aIPS) and the ventral premotor (vPM). Most of the studies proposed that these areas compose the human "mirror system," implicitly suggesting that they contain mirror neurons. Further neuroimaging studies have attempted to characterize the responses of the human "mirror system" during observation, execution, and imitation of different movements. For example, comparing mirror system responses to hand movements that have a goal versus movements that do not (Iacoboni et al. 2005) or in which movements are made by a human arm versus by a robot arm (Gazzola et al. 2007). The majority of these studies interpreted stronger mirror system responses to particular conditions as evidence of mirror neuron preference for particular types of movements rather than others.

There are two concerns with these early experiments and the interpretation of their results. The first is that these experiments were unable to measure exclusive mirror neuron activity. For example, the typical results of passive movement observation and imitation experiments reveal strong responses in many cortical areas, including areas that are not believed to contain mirror neurons (e.g., primary visual cortex). This is clear evidence that many other neurons (e.g., visual neurons) in diverse cortical areas respond strongly during these tasks. Limiting the analysis to

cortical areas that respond during movement execution (by masking out areas that do not) does focus the analysis on more meaningful brain areas but does not solve the problem. As mentioned above, 90% of neurons in “mirror system” areas are not mirror neurons but are rather visual neurons that respond only during movement observation, motor neurons that respond only during movement execution, or visuomotor neurons that respond during both but do not respond selectively to movement identity (e.g., neurons selective for object rather than grasp type (Murata et al. 2000)). Since neuroimaging methods record the average response of very large neural populations, how can one know if the reported responses were generated by the activity of mirror neurons or by the activity of any of these other intermingled neural populations? For example, if a study reports that mirror system areas exhibit stronger fMRI responses during observation of movements with goals than movements without goals (e.g., Iacoboni et al. 2005), does it necessarily mean that mirror neurons responded more strongly? Or could it be that visual neurons responded more strongly because video clips of movements with goals contain richer visual stimuli than video clips of movements without goals?

The second, and perhaps more important concern, is that these studies did not assess movement selectivity. Movement selectivity is a defining physiological signature of mirror neurons in the monkey and is of central importance for the hypothesis that mirror neurons play a role in mapping perception to action. If mirror neurons indeed enable understanding and/or imitation of movements, subpopulations of mirror neurons must distinguish between different movements such that particular mirror neurons must respond selectively to particular movements (Dinstein 2008; Dinstein et al. 2008b). Without clear response selectivity across observation and execution, the mirror neuron theory falls apart. Imagine, for example, a situation where you observe someone executing a “thumbs up” movement. In order to properly understand that movement by simulation, it is critical that you activate the correct motor neurons encoding that particular movement. If you accidentally activate another group of

motor neurons that encode the “thumbs down” movement, you will arrive at the wrong conclusion regarding the intention of the person you are observing. Assessing movement selectivity in mirror system areas is, therefore, a crucial step for confirming or refuting the mirror neuron theory (Dinstein 2008; Dinstein et al. 2008b).

A common method for assessing neural selectivity using fMRI takes advantage of the fact that sensory neurons adapt/habituate when their preferred stimulus is presented repeatedly (Grill-Spector 2006; Grill-Spector and Malach 2001; Krekelberg et al. 2006). Cortical areas containing mirror neurons may, therefore, exhibit reduced fMRI responses when the same movement is presented repeatedly (a single neural population responds repeatedly and adapts) in contrast to when different movements are presented (different neural populations respond and there is no adaptation). Mirror neurons may be expected to adapt during trials where the same movement is repeatedly observed, repeatedly executed, observed and then executed, or executed and then observed (cross-modal adaptation). Showing such response selectivity in mirror system areas would be strong evidence for the existence of mirror neurons and would also offer a tool for further characterizing their selectivity for particular types of movements. For example, does adaptation occur across different movements that share a common goal (waving “hello” with either left or right hand) but not across different movements that do not (waving “hello” with left hand and waving “come here” with right hand). Such results would offer important evidence regarding the movement characteristics that are encoded by human mirror neurons.

Several recent studies have used fMRI adaptation protocols to assess response selectivity for different hand movements. These studies have reported visual (Dinstein et al. 2007; Hamilton and Grafton 2006; Shmuelof and Zohary 2005), motor (Dinstein et al. 2007; Hamilton and Grafton 2009), and cross-modal (Chong et al. 2008; Kilner et al. 2009; Lingnau et al. 2009) adaptation in mirror system areas during observation and execution of different hand movements. While some of the studies used object-oriented hand

movements (e.g., pulling, gripping, and grasping objects) (Hamilton and Grafton 2006; Kilner et al. 2009; Shmuelof and Zohary 2005), others used symbolic or gestural hand movements (e.g., thumbs up, rock, paper, scissors) (Chong et al. 2008; Dinstein et al. 2007; Hamilton and Grafton 2009; Lingnau et al. 2009). A consistent finding across all studies was that mirror system areas exhibited visual adaptation when the same movement was observed repeatedly and motor adaptation when the same movement was executed repeatedly. Such adaptation could hypothetically take place in two independent neural populations, one visual and the other motor, or in a single neural population of mirror neurons. While these results do not prove the existence of mirror neurons in humans, they do suggest that neurons with visual and motor movement selectivity are intermingled within mirror system areas in humans. This is somewhat encouraging because a fundamental feature of cortical organization is that neighboring neurons are strongly connected and perform common computations. The existence of neighboring intermingled neurons with movement selectivity, therefore, does suggest the existence of some form of mirror mechanism in humans. More persuasive is a recent study using object-oriented hand movements, which reported visual and motor adaptation as well as both forms of cross-modal adaptation in mirror system areas (Kilner et al. 2009). Cross-modal adaptation could only take place in a mirror neuron population that adapts when observing and then executing or when executing and then observing the same hand movement. Taken together, this evidence suggests that mirror neurons do exist in humans and that, similarly to mirror neurons found in the macaque monkey, they respond selectively to movements involving objects. It is not clear whether there are mirror neurons in humans that respond selectively to gestural and/or communicative movements.

Another method for assessing neural selectivity using fMRI involves the comparison of voxel-by-voxel response patterns using different classification techniques. This analysis is particularly useful in situations where subpopulations of neurons with different selectivity are distributed

unevenly within multiple neighboring voxels. In such cases, each subpopulation is expected to generate a unique fMRI response pattern that appears in trials containing its preferred stimulus and is distinct from the pattern generated by neighboring subpopulations in trials containing their preferred stimuli. This technique was successfully used, for example, to study the selectivity of human visual cortex neurons to visual orientations (Kamitani and Tong 2005), visual motion (Kamitani and Tong 2006), and visual categories (Haxby et al. 2001).

Two recent fMRI studies have used this technique to assess selectivity for different hand movements in mirror system areas during both observation and execution. The main difference between the studies was that in the first, subjects observed and executed symbolic hand movements (rock, paper, or scissors), while in the second, movements were oriented toward objects (grasping or pulling objects). The first study reported that classification of the fMRI response patterns in aIPS enabled accurate identification of the movement observed or performed on each trial. This shows that each movement was associated with a unique spatial response pattern generated by a unique and selective neural subpopulation (Dinstein et al. 2008a). If aIPS were to contain only mirror neurons, an identical fMRI response pattern would be expected during observation and execution of the same movement. This, however, was not the case as accurate movement identification by response pattern was possible only within the visual or motor modality but not across modalities. The second study, using object-oriented movements, did report accurate movement classification in aIPS both when assessing responses within each modality as well as across the two modalities (Oosterhof et al. 2010). These results seem to suggest a dissociation between responses to symbolic hand movements and object-oriented hand movements. Again, clear evidence supporting the existence of mirror neurons in humans seems to exist when considering object-oriented movements rather than gestural movements.

To conclude, the adaptation and classification studies seem to present converging evidence

suggesting that, like the monkey, humans have mirror neurons that respond selectively to different movements involving object manipulation. The case for mirror neurons selective for gestural and communicative movements seems less clear and is somewhat at odds with the mirror system hypothesis suggesting that mirror neurons enable social communication. Proper social communication is mostly based on correct interpretation of body language, gestures, and expressions rather than interpretation of object-oriented movements such as grasping or pulling.

Pathophysiology

Mirror System Dysfunction in Autism?

Impaired social interaction is one of the three core behavioral symptoms of autism (DSM-IV-TR 2000). Impaired imitation may also be a characteristic of autism, although there is controversy regarding its consistency (Hamilton et al. 2007). According to the “dysfunctional mirror system theory of autism,” these behavioral problems are caused by dysfunctional mirror neurons that impair the individual’s ability to simulate observed movements/actions (Williams et al. 2001). The idea is that inaccurate simulation or perhaps even a complete lack of simulation disrupts the ability to appropriately interpret the goals, intentions, and emotions associated with observed hand gestures, facial expressions, and body language of others. This theory has received an extraordinary amount of attention in both the popular press (Blakeslee 2006; Ramachandran and Oberman 2006) and the scientific press (Buccino and Amore 2008; Iacoboni and Dapretto 2006; Iacoboni and Mazziotta 2007; Keysers and Gazzola 2006; Le Bel et al. 2009; Oberman and Ramachandran 2007; Perkins et al. 2010; Rizzolatti and Fabbri-Destro 2008, 2009; Rizzolatti et al. 2009; Williams 2008; Williams et al. 2001). The empirical evidence supporting it, however, has been remarkably sparse and inconsistent.

Evidence in support of the dysfunctional mirror system theory of autism has come from several EEG/MEG (Honaga et al. 2010; Martineau

et al. 2008; Nishitani et al. 2004; Oberman et al. 2005) and fMRI (Dapretto et al. 2006; Hadjikhani et al. 2007; Schulte-Ruther et al. 2011) studies that have reported significantly weaker responses in mirror system areas of individuals with autism, as compared to controls, during passive observation or active imitation of hand movements or facial expressions. Weaker mirror system responses in autism have been interpreted as evidence for weak mirror neuron responses that are unable to complete the proper simulation processes supposedly needed to understand the meaning of the observed movements or imitate them. There have been, however, a similar number of EEG/MEG (Avikainen et al. 1999; Fan et al. 2010; Oberman et al. 2008; Raymaekers et al. 2009) and fMRI (Dinstein et al. 2010; Marsh and Hamilton 2011; Williams et al. 2006) studies that have reported equivalent mirror system responses in autism and control groups and one fMRI study that has even reported significantly stronger mirror system responses in autism as compared to controls during the observation of hand movements (Martineau et al. 2010). As a side note, it is interesting that all of the studies above, regardless of the reported response strength in autism, used gestural hand movements, finger tapping, or facial expressions rather than object-oriented movements. The mixed results were, therefore, not a consequence of using different movements.

Numerous methodological issues could have generated the heterogeneous results described above. For example, it is difficult to control the behavior of subjects during EEG and fMRI experiments. When subjects are asked to imitate a movement, delays in the timing or length of movement execution may greatly impact the estimated brain response. If subjects with autism imitate the movement later or more slowly than controls, their estimated brain responses will seem weaker because of a temporal mismatch between the expected and actual brain response. In such a situation, reduced mirror system responses would have little to do with mirror system abnormalities in autism and a lot to do with a different choice of behavioral response in

autism. Regardless of the true reason underlying the reduced responses, the results discussed above clearly show that individuals with autism can exhibit normal mirror system responses under some experimental conditions (Avikainen et al. 1999; Dinstein et al. 2010; Fan et al. 2010; Marsh and Hamilton 2011; Martineau et al. 2010; Oberman et al. 2008; Raymaekers et al. 2009; Williams et al. 2006). This argues against the claim of a generally dysfunctional mirror system in autism.

As discussed previously, perhaps the biggest concern with the interpretation of the studies above is their lack of ability to isolate mirror neuron responses and their lack of ability to assess movement selectivity. With this in mind, the reports above actually say very little about mirror neuron integrity in autism. Weak, normal, or excessive fMRI responses in mirror system areas could be generated by different combinations of visual neuron responses during observation and motor neuron responses during imitation. There is, therefore, no reason to assume that any of the reported differences in fMRI responses between autism and control groups were due to differences in mirror neuron responses. Furthermore, these studies do not offer any evidence for determining whether neural subpopulations in mirror system areas exhibit normal or abnormal movement selectivity in autism. The “dysfunctional mirror system theory of autism” would predict weak or even a complete lack of movement-selective responses in autism, which would be expected to yield an impaired simulation process. Is this indeed the case?

A recent fMRI adaptation experiment attempted to address this particular question and reported that mirror system responses in individuals with autism exhibited equivalent movement selectivity to that found in controls (Dinstein et al. 2010). In this study, individuals with autism exhibited not only strong mirror system responses during the observation of symbolic hand movements (e.g., rock, paper, scissors, thumbs up), but they also exhibited adaptation in trials where the same movement was repeatedly observed or repeatedly executed. These adaptation results were interpreted as evidence for typical

movement selectivity in mirror system areas of individuals with autism. Since selectivity is one of the two defining characteristics of mirror neuron responses, these data offer strong evidence against a general mirror system dysfunction in autism. All of the high-functioning individuals with autism who participated in this study exhibited ADOS scores that were well above the criteria for autism rather than the milder diagnoses of PDD-NOS and Asperger’s syndrome. These results, therefore, cannot be attributed to less severe behavioral symptoms in the participating subjects. Note that this study, like all other mirror system studies in autism, used gestural hand movements rather than object-oriented movements. Since cross-modal adaptation is a key signature of mirror neurons, which seems to be apparent only in responses to object-oriented movements, it would be important to also determine the integrity of such responses in autism.

Finally and more generally, it is important to consider how useful it is to describe autism as a disorder of one particular neural population such as mirror neurons. Most of the symptoms associated with autism do not seem related to mirror neurons at all. These include the core diagnostic symptoms of repetitive behaviors and language impairments (DSM-IV-TR 2000) as well as the commonly described secondary symptoms, which include sensory hypo/hypersensitivities (Jones et al. 2003; Kanner 1943; Minshew and Hobson 2008; O’Neill and Jones 1997), sleep problems (Cortesi et al. 2010; Richdale and Schreck 2009), and gastrointestinal problems (Buie et al. 2010a, b). Furthermore, much of the research into autism suggests that multiple neural abnormalities exist in many brain areas. fMRI studies have reported abnormally weak neural responses in autism not only in mirror system areas but also in superior temporal sulcus (Pelphrey and Carter 2008), face processing areas (Dawson et al. 2005), “mentalizing” areas (Marsh and Hamilton 2011), and cingulate cortex (Chiu et al. 2008), among others. Reports of abnormal functional (Minshew and Keller 2010) and anatomical (Courchesne et al. 2007) connectivity have suggested that neural communication and synchronization may be altered (mostly decreased) across multiple brain areas in autism. Developmental

studies have reported early overgrowth of gray and white matter in frontal cortex, temporal cortex, and cerebellum, which is followed by arrested growth during adolescence (Courchesne et al. 2004). Genetic studies have reported numerous mutations, deletions, and single-nucleotide polymorphisms that may increase the risk of developing autism. Most of the associated genes are involved in general cellular development including dendritic growth and synaptic maturation (Geschwind and Levitt 2007). Such genetic abnormalities would be expected to create widespread excitation-inhibition imbalances (Rubenstein and Merzenich 2003) as well as abnormalities in the neural architecture and connectivity of multiple brain areas, thereby, impacting multiple behaviors (Bourgeron 2009). Finally, individuals with autism have abnormally high chances of developing epilepsy throughout life. It is estimated that 20–30% of individuals with autism have epileptic seizures at some point in life and that up to 60–70% may exhibit abnormal epileptiform-like EEG recordings (Tuchman and Rapin 2002). When considering this larger breadth of evidence, it seems that describing autism as a disorder of mirror neurons may not be particularly useful in capturing the multitude of behavioral and physiological elements associated with the disorder.

To conclude, despite its surprising popularity (Iacoboni and Dapretto 2006; Iacoboni and Mazziotta 2007; Rizzolatti and Fabbri-Destro 2008, 2009; Williams et al. 2001), at present, the evidence supporting the “dysfunctional mirror system hypothesis of autism” seems rather sparse, inconsistent, and controversial (Baird et al. 2011; Dinstein et al. 2008b; Hamilton 2009; Hamilton et al. 2007). Further assessment of response selectivity in autism using adaptation and classification techniques is warranted in order to reveal useful data that will support or refute the hypothesis. The integrity of mirror system selectivity in autism should be tested with gestural hand movements and facial expressions, which seem particularly relevant to the social symptoms of autism, as well as with object-oriented movements, which seem to be the most effective movements for generating mirror neuron activity in both monkeys and humans.

Mirror Neurons

David Saunders

Yale Child Study Center, New Haven, CT, USA

Synonyms

[Mirror neuron system](#)

Definition

Mirror neurons were first reported in macaque monkeys in 1992 and subsequently identified in humans. First localized to the ventral premotor area, the Mirror Neuron System (MNS) has also been linked to the inferior parietal lobule, the dorsal premotor, and primary motor cortex, among other regions. Mirror neurons modulate their activity in at least two instances: when an individual executes a motor action and when observing the same (or similar) action performed by another individual. In this way, their activity is modulated by both action execution and observation of an action, which distinguishes mirror neurons from other neurons that discharge with either execution or observation, but not both. Observed actions are directly mapped onto the MNS of the observer, suggestive of the intimately intertwined natures of action execution and observation. Further, it suggests that the interpretation of the actions of others may require the use of our own motor system.

The MNS has been proposed as a potential etiology for Autism Spectrum Disorder (ASD), though it is a subject of fervent debate. The MNS is thought to encode the goal of an action, not just the motor component, meaning that the MNS contains a mechanism by which one understands other people, and for imitating them. As such, the MNS is thought to be a key component of social cognition. Because poor social cognition is a hallmark of ASD, researchers have theorized that a dysfunctional MNS may be a neurobiological basis for the disorder. This hypothesis is commonly called the Broken Mirror Theory (BMT). One researcher distinguishes three

different variants of the BMT, each of which makes a different claim about the mechanism by which a disrupted MNS contributes to ASD. The imitation hypothesis suggests that an altered MNS leads to poor self-other mapping that is thought to be at the heart of abnormalities in social cognition in ASD (e.g., theory of mind). The simulation hypothesis is predicated on the notion that the MNS provides the basis for simulating other individuals. A disrupted MNS, it is theorized, leads to an inability to simulate not only actions but also mental and emotional states. The action chain variant rests on the claim that some neurons within the MNS are only activated when an action is embedded in a sequence or chain. When a neuron of this type is activated at the beginning of an action sequence, the individual is able to predict how the entire chain of events will unfold. Disruptions in this specific part of the MNS lead to an inability to understand how a given action is embedded in a particular context, thus leading to difficulties in social cognition.

Though the data is far from conclusive, evidence for an abnormal MNS in individuals with ASD can be found across multiple methodologies, including electroencephalography, magnetoencephalography, transcranial magnetic stimulation, eye tracking, structural MRI, and functional MRI.

Mirtazapine

Rizwan Parvez

Yale Child Study Center, New Haven, CT, USA

Synonyms

[Remeron](#)

Definition

An antidepressant medication. Mirtazapine exerts its antidepressant effect by inhibiting alpha-2 adrenergic presynaptic receptors, resulting in increased levels of serotonin and norepinephrine. This is an alternate mechanism to that used by SSRI medications. Additionally, mirtazapine blocks H-1 histamine receptors, which may contribute to its sedating effects. Mirtazapine is also associated with increased appetite, higher risk of weight gain, dry mouth, and constipation.

Mismatch Negativity

Benjamin Aaronson¹ and Raphael Bernier²

¹Psychiatry and Behavioral Sciences, UW Autism Center, University of Washington, Seattle, WA, USA

²Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, USA

Definition

The mismatch negativity (MMN) is an event-related potential (ERP) evoked in response to a perceived change in sensory stimuli. It is commonly elicited in an oddball paradigm in which a standard stimulus is paired with a deviant stimulus, the standard being presented the majority of instances. It generally occurs 150–250 ms after the presentation of the deviant stimulus, though in children its latency is delayed to between 200 and 300 ms. The MMN is typically evaluated by calculating a difference wave, computed by subtracting the ERP in response to the standard stimulus from the ERP to the deviant stimulus.

Historical Background

Electrophysiology provides an avenue to examine mental functioning that may not be manifested behaviorally. It allows for the investigation of aspects of cognition, perception, and other biological bases for behavior. This is especially useful in assessing infant and clinical populations that may lack the requisite capacities for expression.

Electroencephalography (EEG) consists of recording the brain's electrical activity. In humans, this is accomplished by placing electrodes at various locations on the scalp. Electrical surface recordings are limited in terms of spatial resolution, in that it is difficult to precisely identify the source of electrical fields in the brain. However, electrical recordings can provide excellent temporal resolution, revealing the brain's response effectively in real time.

Event-related potentials (ERPs) are electrical activity time-locked to a particular event. ERPs are commonly utilized to assess the brain's processing of external stimuli. In order to demonstrate that the recorded response is related to the target event and not to extraneous influences, a series of trials are averaged together to create a composite waveform. Waveforms can be averaged across trials within a single subject, as well as across individuals and groups.

The mismatch negativity (MMN) was first described by Näätänen and colleagues in a 1978 paper examining negative potentials via EEG in response to deviations in tone frequency. The MMN refers to an automatic neurological response to a change in auditory stimuli, represented by a peak difference generally observed 150–250 ms poststimulus. The degree of variance between the stimuli required to elicit the neural MMN response is approximately the difference required for behavioral discrimination.

ERPs such as the MMN are assessed in terms of amplitude – power or voltage, and latency – timing. MMN amplitude has been associated with degree of deviant contrast and accuracy of discrimination, with increases in amplitude associated with greater contrast and greater discrimination, and decreases in amplitude associated with reduced contrast and reduced discrimination. Earlier latency has also been associated with greater stimulus contrast.

The MMN has been demonstrated in response to wide variety of stimuli. These include computer-generated sounds such as sinusoidal tones and musical chords, as well as human speech sounds such as vowels and consonant phonemes. Among these stimuli, the MMN has been shown to be sensitive to changes in frequency, pitch, intensity, duration, and presentation order. More recently, researchers have begun to explore MMN equivalents in response to visual and olfactory stimuli.

The MMN has been consistently elicited independent of directed attention. Further, it has been demonstrated in the context of multiple-competing auditory streams. However, competing auditory stimuli can diminish MMN amplitude. Competing visual stimuli generally do not impact

the MMN. Conversely, variations in background noise which elicit the MMN response can impact attention, reorienting a person to an anomalous environmental stimulus.

This highlights an important developmental and operational function of the MMN. The MMN represents the brain's perception of an anomalous event. It is often followed by a positive peak occurring between 250 and 300 ms. This positive potential, known as the P3a, is an electrophysiological marker of novelty and represents the automatic reorienting of attention. Thus, the MMN is a functional precursor, evidencing the automatic perception of a deviant stimulus, leading to the actual reorienting of attention as evidenced by the P3a (for review, see Friedman et al. 2001).

The source of the MMN appears to be in the auditory cortex, as evidenced by scalp distribution data, studies of magnetic encephalography, intracranial recordings, and cases of brain lesions. Additional data reveal the frontal lobe as a contributing generator. It is suggested that the frontal lobe involvement may be related to attentional switching associated with the MMN (Alho 1995). Other studies have evidenced that the MMN response elicited by speech sounds is primarily sourced in the left temporal lobe, whereas MMN in response to nonspeech sounds is primarily sourced in the right temporal lobe (Kujala 2007).

Various studies have demonstrated the effects of training on the MMN. Individuals, who at the beginning of a session could not behaviorally discriminate between divergent stimuli and failed to exhibit a corresponding MMN, later learned through exposure to behaviorally discriminate between the stimuli and exhibited a parallel MMN response. This further demonstrates the value of the MMN as a real-time index of learning and discrimination.

Current Knowledge

As an electrophysiological index of auditory perception that closely matches behaviorally observed capabilities, the MMN provides a

valuable tool in the biological assessment of language and associated capacities. It has accordingly been utilized in the scientific examination of autism spectrum disorders (ASD). Given that deficits in language and social orienting are prominent features of autism spectrum disorders, a contributing factor in these impairments may be an inability to perceive and process contrasting auditory stimuli, especially speech sounds. Thus, the MMN provides a potential method for exploring auditory processing in ASD.

A limited number of studies have examined the MMN in ASD. Results from these studies have not been entirely consistent, though a variety of studies have demonstrated MMN and other ERP differences in ASD subjects as compared with controls. These have included differences in amplitude, latency, and hemispheric distribution. Divergent findings may be due to differences in paradigm design, participant characteristics, and diagnostic inclusion criteria.

A series of studies have shown enhanced MMN in ASD (Ferri et al. 2003; Jansson-Verkasalo et al. 2003; Kujala et al. 2007, 2010; Lepisto et al. 2005, 2006, 2007, 2008). The most common finding among these studies is an increase in amplitude, particularly over the right hemisphere. Some studies have also evidenced shorter latencies (Ferri et al. 2003; Jansson-Verkasalo et al. 2003; Kujala et al. 2007; Lepisto et al. 2005, 2007). This is consistent with behavioral findings indicating heightened auditory discrimination abilities in ASD (Gomot et al. 2002). Enhanced perceptual ability may in fact adversely impact language learning, reflecting an inability to ignore irrelevant stimuli.

Other studies have failed to show MMN or shown diminished MMN amplitude in ASD (Dunn et al. 2008; Kuhl et al. 2005; Lepisto et al. 2005, 2006). These findings are generally interpreted to evidence reduced discrimination, with obvious implications for language deficits.

In a noteworthy study, Kuhl et al. (2005) examined MMN and behavioral speech preferences in a sample of school-aged children with and without ASD. The paradigm involved an auditory preference task, assessing a child's preference for speech or nonspeech stimuli, and an ERP task,

assessing MMN responses to changes in consonant-vowel speech sounds. On a group level, children with ASD exhibited a preference for nonspeech sounds and failed to exhibit MMN. Typically developing controls, chronologically and mentally age-matched, exhibited a preference for speech sounds and exhibited a typical MMN response. Interestingly, when the ASD group was subdivided based on speech preference, the children with ASD who preferred speech sounds exhibited MMN responses similar to typical controls. According to the authors, this finding provides evidence for a relationship between phonetic learning and social interaction, suggesting that social interest may have a direct impact on language learning. This further substantiates the MMN as a neural correlate of broader language capacities with potential social implications.

Another study replicated previous findings demonstrating diminished MMN amplitude in ASD subjects in response to unattended stimuli. However, when subjects were instructed to attend to the stimuli, the MMN for ASD subjects was similar to controls (Dunn et al. 2008). This indicates that auditory processing that occurs automatically in typical individuals may require attention to be operative in ASD. This presents a significant disadvantage noting that direct attentional capacities are inherently limited, and thus processing capability may suffer in complex environments. This study also provided an explanation for discrepant findings in previous literature, noting that a prominent study that failed to show MMN differences in ASD had procedurally instructed participants to attend to the stimuli.

MMN may change over time in ASD. Two studies were conducted utilizing the same experimental paradigm with adults and children respectively, diagnosed with Asperger's. MMN responses were recorded to changes in duration and pitch. Both samples demonstrated enhanced MMN to pitch changes. However, duration changes showed a diminished MMN in children and an enhanced MMN in adults (Lepisto et al. 2006, 2007). These findings imply that MMN may have a complex developmental course in ASD.

Many studies revealed differences in hemispheric distribution in ASD as compared with control samples (Gomot et al. 2002; Jansson-Verkasalo et al. 2003; Kujala et al. 2007, 2010; Lepisto et al. 2006, 2007). As a trend, these included enhanced responses over the right hemisphere and diminished responses over the left hemisphere. Whereas control groups often exhibited no hemisphere dominance for the MMN, ASD groups exhibited right hemisphere dominance (Kujala et al. 2007; Lepisto et al. 2006, 2007). These abnormal patterns of MMN lateralization may reflect impaired interhemispheric processing.

Future Directions

Some of the difficulties in interpreting the multiplicity of findings with regard to the MMN in ASD are likely related to varying diagnostic criteria across studies. This is an issue that affects ASD research across the board, given the etiological and clinical heterogeneity of ASD. Utilizing instruments that involve standardized behavioral observation and standardized interviewing, in conjunction with expert clinical judgment, can better constrain research populations ensuring more consistent ASD samples.

Though increased amplitude and shorter latency are associated with greater discrimination, when an increase in amplitude is coupled with extended latency or, conversely, when a decrease in amplitude is coupled with shorter latency, the specific implication with regard to discrimination is unclear. Though differences in amplitude and latency in ASD manifest "abnormal processing," future research may be able to determine more precisely how variations in electrophysiological components relate to global processing.

The MMN can be recorded in young infants reliably between 3 and 5 months. Some studies have even elicited MMN correlates in fetuses. As more specific clinical electrophysiological profiles emerge, MMN may be a promising tool for revealing clinical disorders early in development, leaving open the prospect of increasingly early intervention.

Training and learning have been shown to improve MMN responsiveness. This may indicate an opportunity for intervention in clinical disorders. In ASD specifically, directed attention has been shown to positively impact the MMN (Dunn et al. 2008). Future research could focus on the evaluation of intervention effects in clinical populations using the MMN as a marker. This may provide information that can be translated into evidence-based intervention methodologies, as well as general information about the nature of auditory processing deficits in these populations.

Researchers have also begun exploring methods for assessing MMN at the single-subject level. Currently, the MMN provides a reliable tool for examining group differences in clinical populations. As this methodology progresses, it may be able to reliably identify an individual's auditory discrimination capacity. Such an electrophysiological marker could have useful implications for diagnosis and intervention in ASD.

Misophonia

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of
Child Psychiatry, Pediatrics and Psychology,
Yale Child Study Center, School of Medicine,
Yale University, New Haven, CT, USA

Synonyms

[Hatred of sound](#); [Sound sensitivity](#)

Definition

Misophonia is characterized by an individual's sensitivity to/negative reaction to a sound or sounds (Cavanna and Seri 2015). It can be observed in isolation or in combination with other disorders, like autism spectrum disorder. Unfortunately, research on the condition is rather limited and there is not yet agreement on how this phenomenon/condition is best conceptualized, i.e., as a condition in its own right or as a feature of other disorders. The condition is not yet recognized in official diagnostic systems. The term literally means "hatred of sound" and was first proposed in 2000 and noted the combination negative emotions/reactions to specific sound(s) as the hallmark feature (Cavanna and Seri 2015).

Given the lack of consensus on the nature of the condition and its definition, the literature on this condition/phenomenon is rather limited. In some cases, the condition's severity or presentation presents a major problem for the individual, and various treatment strategies have been proposed, e.g., cognitive behavior therapy or exposure therapy (McGuire et al. 2015; Kamody and Del Conte 2017; Bruxner 2016).

The sounds that trigger the negative reactions can be either loud or soft. In one study, the most commonly reported sounds relate to eating and/or the mouth, e.g., sounds of eating, chewing, whispering (Bruxner 2016).

Understanding of the trigger sound(s) remains limited. Individuals with the condition may be quite aware that it is disruptive. Often attempts to avoid the sound triggers can lead to unanticipated avoidance behaviors that further restrict interaction with others.

Given the lack of consensus on the nature of the condition, there are no data, at present, on epidemiology, gender differences, and so forth. While, in some respects, clearly related to anxiety disorders, the fundamental nature of Misophonia remains to be established. As research on this condition/phenomenon continues, it is likely that there will be greater clarity on issues including (a) best approaches to definition, (b) clinical features and associations with other disorders, (c) epidemiology and differences in rates by gender, race, and so forth, and (d) frequent co-morbidities of the conditions.

Mitochondrial Deficits/Disorders

Jonathan Kopel

Synonyms

Organelle

Definition

Mitochondria are the central hub for energy metabolism in the cell providing the main source of ATP and TCA intermediates for several anabolic and catabolic processes (Siddiqui et al. 2016). Mitochondrial dysfunction can occur due to genetic or biochemical abnormalities affecting ATP synthesis. Specifically, several reports showed abnormalities in autism spectrum disorder (ASD) patients involved in phospholipid production (Siddiqui et al. 2016). Further analysis of N-acetyl-aspartate, a marker for mitochondrial dysfunction, showed elevations in the white and gray matter cortex of ASD patients (Siddiqui et al. 2016). Other studies examining the electron transport chain of mitochondria isolated from ASD patients showed decreases in metabolic activity of several enzymes and transport complexes throughout the brain (Siddiqui et al. 2016). This dysfunction of enzymes and transport activity is believed to contribute to the increased reactive oxygen species and oxidative stress observed in ASD neurological studies. Several mutations associated with the electron transport chain, including complexes III, IV, and VII, showed decreased activity and expression in ASD patients. The results suggest global metabolic abnormalities within the mitochondria, and perhaps the cytoplasm may alter neuronal activity and connectivity within the brains of ASD patients.

Mobile Work Crew Model

Michelle Lestrud
The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Synonyms

Community work crew; Community-based work team; Enclave; Supported employment group; Work team

Definition

A mobile work crew model follows the practice of placing together several individuals to work in the community as a team or “crew.” Typically, the individuals have a disability and are accompanied by a nondisabled support person or job coach. This type of work group falls under the category of supported employment. The mobile work crews may work at various locations but often specialize in a specific area such as janitorial services, lawn care, maintenance jobs, etc. These jobs are in the community but may not be integrated with employees outside the work crew and may not require competitive rates of production. The mobile work crews are often associated with an agency providing vocational or day services to people with autism. In some cases, individuals with autism may be able to learn needed vocational skills while on a mobile work crew to lead to a higher level of employment or competitive employment.

Möbius Syndrome

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Moebius syndrome](#)

Definition

This very rare congenital disorder (perhaps 1 in 100,000 births) is characterized by facial paralysis and a lack of ability to move the eyes from side to side. This is a result of failure of normal development of the sixth and seventh cranial nerves. Sometimes, other facial nerves are also affected – if the eighth nerve is affected, hear loss is present as well.

Abnormalities in other areas can include problems with the chest wall and extremities. Given the lack of facial expression, most individuals with the condition are assumed not to have normal intelligence, but this is not correct. The condition is named after the neurologist who described it in the last 1800s. Treatment is supportive in nature. The etiology of the syndrome remains unclear with some suggestion of genetic links as well as links to teratogenic drugs such as thalidomide.

A few studies, mostly case reports and at least one case series, have suggested a potential increased risk for autism. The significance of this association remains unclear.

Modeling

Cheryl Smith Gabig

Department of Speech, Language, and Hearing Sciences, Lehman College/The City University of New York, Bronx, NY, USA

Synonyms

[Example, demonstration; Representation](#)

Definition

Modeling refers to an intervention procedure that provides an example or explicitly demonstrates a verbal or social behavior targeted for intervention. The demonstration serves as a standard for imitation or comparison by the learner by providing an example of the structure or content of a targeted language or social behavior. The modeled demonstration can be presented either verbally or visually through pictures or videos. The modeling procedure may take one of six forms: model-recast, model-prompt-imitation, aided modeling, interactive modeling, in vivo modeling, and video modeling.

- Model-recast is a method that provides a model of the structural or semantic properties of language for the child by recasting a child's utterance during discourse interaction. The recast/model supplies missing grammatical aspects or semantic relationships while maintaining the child's central meaning. For example, if the child omits the auxiliary verb and present progressive tense marker when

saying “doggie eat,” the adult recast or model would maintain the meaning but provide the missing grammatical markers, as in “The doggie is eating.”

- Model-prompt-imitation is an elicitation procedure that presents a target language or social behavior and elicits the targeted behavior from the child in a model-prompt-imitation format. For example, if the target language behavior is the appropriate response to question forms, the clinician or adult may model the expected response and prompt the child to imitate as in “What is your name?” followed by the model “My name is Jack,” and then a prompt to imitate: Tell me: “My name is Jack.”
- Aided modeling occurs during instruction in the use of an augmentative and alternative communication (AAC) device wherein the adult uses the AAC device as well as speech to demonstrate the expected communication output.
- Interactive modeling facilitates language development in a socially interactive format. The adult follows the child's lead and provides a verbal gloss of the actions and focused attention to objects by the child. For example, if a child looks at or picks up an object, the adult verbalizes or glosses the child's actions or attention focus by modeling the appropriate language, for example, “Ball,” “This is a ball.” If the child performs an action on the object, the adult would provide a language model or gloss of the action, such as “throw ball,” “Jack is throwing the ball.”
- In vivo modeling involves the real-life situational observation of typical persons performing a task.
- Video modeling involves a child viewing a video demonstration of a target behavior that serves as a model for imitation and comparison.

Modeling has been found to be an effective intervention technique for children and adolescents with autism, especially the use of model-prompt-imitation, aided modeling, in vivo modeling, and video modeling. Less is known

regarding the use of the model-recast method in teaching verbal skills to children with autism spectrum disorders.

Abbreviations

AAP	American Academy of Pediatrics
ASD	Autism spectrum disorder
CESDD	Checklist for Early Signs of Developmental Disorders
ESAT	Early Screening of Autistic Traits questionnaire
FUI	Follow-up interview
NPV	Negative predictive value
PEDS	Parents' Evaluation of Developmental Status
PPV	Positive predictive value
Se	Sensitivity
Sp	Specificity

Description

The Modified Checklist for Autism in Toddlers (M-CHAT; Robins et al. 1999a) is a screening measure developed to identify young children with an elevated risk for autism spectrum disorder (ASD) through parent report. This instrument is one of the most commonly used screening instruments for ASD in toddlers worldwide.

The checklist was developed and validated for children between 16 and 30 months old. Parents are asked to answer 23 yes/no questions about the usual behavior of their child. Responses of parents indicating typical development are balanced. Children screen positive for ASD if they fail three or more items in total or if they fail two or more out of six critical items, derived from discriminant function analysis. These six critical

items ask about the child's interest in other children, response to name being called, following a point of the parent, own pointing and showing to indicate interest, and imitation (Robins et al. 2001b).

In addition to the parent report, a follow-up interview (M-CHAT FUI; Robins et al. 1999b) was designed to ascertain responses of parents for screen positive children. Parents are asked to clarify the items failed by their child in a structured format. To ensure presence or absence of specific behaviors, parents are asked to give some examples of these behaviors. In addition, detailed information about the frequency of the behaviors is elicited. Including this follow-up interview in the screening lowers the amount of false positive screens, without compromising the sensitivity of the instrument (see also the section on “[Psychometric Data](#)”). This interview can be conducted in person or over the phone (Robins and Dumont-Mathieu 2006; Robins et al. 2001b).

Historical Background

The M-CHAT is an adaptation and extension of the Checklist for Autism in Toddlers (CHAT; Baron-Cohen et al. 1992; Baron-Cohen et al. 1996). The CHAT was originally designed to screen for autism, not ASD, in 18-month-olds. The child's general physician or health visitor completes the checklist, for example during the 18-month routine check-up. The CHAT consists of two parts: nine parent questions (part A) and five observation items that have to be administered by trained professionals (part B). For more details about this measure, see entry ► “[CHAT](#).”

The M-CHAT modified the CHAT into an instrument completely reliant on parent report, because this may be more accurate than a brief observation by a professional (Robins and Dumont-Mathieu 2006). The first nine items of the CHAT (part A) were included as such in the M-CHAT. In addition, 21 new items were formulated to compensate for the loss of the observation part (part B) of the CHAT, but also to broaden the signs of ASD included in the checklist. The authors of the M-CHAT wanted to identify a

greater range of children on the autism spectrum, not solely children with autism. Based on preliminary analyses of the first 600 children, eight items were dropped because they lacked discriminant power or because parents misunderstood their content. In addition, one item about social referencing was added, leading to the final 23 items in the checklist (Robins et al. 2001b).

Since the development of the M-CHAT, the instrument has been translated into more than 30 languages, including Arabic, French, Dutch, German, Spanish, Portuguese, Chinese, and Japanese. The checklist itself, the follow-up interview, and the different translations are available for free download for clinical, research, and educational purposes (see www.mchatscreen.com). For use with Chinese and Japanese children, some adaptations to the M-CHAT were made. For the Japanese version, the M-CHAT was translated and some illustrations were added to the items about declarative pointing, showing, gaze following, and social referencing, in order to encourage caregivers to notice negative symptoms (Inada et al. 2011). For Chinese children, Wong et al. (2004) combined the M-CHAT and CHAT into a new screening measure: the CHAT-23. This instrument incorporates a Chinese translation of the 23 items of the M-CHAT (part A) and the five observation items of the CHAT (part B). The authors suggest using part A as a Level 1 screening instrument for use in the general population, followed by administration of part B as a Level 2 screening instrument for screen positive children on part A. For more details on the CHAT-23, see the entry ► “[CHAT](#).”

Psychometric Data

Discriminant Validity

Several studies have evaluated the psychometric properties of the M-CHAT as a screening instrument for ASD in toddlers. The original validation study included 1,122 children from a nonselected population and 171 high-risk children screened through early intervention service providers. All children were between 16 and 30 months old. There were 39 children identified with ASD in

this sample: three from the unselected sample and 36 from the high-risk group. None of the children in this study who were evaluated after screening positive had an entirely typical development. Robins et al. (2001b) estimated the psychometric properties of the M-CHAT through discriminant function analysis classification based on known diagnoses of ASD before follow-up of the entire sample. The sensitivity (Se) was estimated at .87, the specificity (Sp) at .99, the positive predictive value (PPV) at .80, and the negative predictive value (NPV) at .99. They used this approach because calculation of Se and Sp depends on follow-up of both positive and negative screen children to ascertain diagnosis in all children and follow-up was still pending. Dumont-Mathieu and Fein (2005) reported estimates on the Se and Sp of the M-CHAT based on the first 940 children of the original sample who were rescreened at age 4. This rescreen resulted in six possible missed cases. Se was estimated at .85 and Sp at .93.

A study by Kleinman et al. (2008) showed that the PPV of the M-CHAT depends on the inclusion of the follow-up interview and on the sample of children to which it is applied. These authors screened a completely new sample of children between 16 and 30 months old: 3,309 low-risk children from an unselected sample and 484 high-risk children from early intervention service providers. For the total sample, the PPV after a positive screen on the M-CHAT was only .36. However, if this positive screen was also confirmed by the follow-up interview, the PPV increased to .74. There were also some differences found in PPVs between the low- and high-risk groups. Without follow-up interview, the PPVs were .11 and .60 for, respectively, the low- and high-risk group. When positive screens were confirmed with the follow-up interview, the PPVs were .65 and .76 for, respectively, the low- and high-risk group.

Pandey et al. (2008) added 2,983 new children between 16 and 30 months old to the Kleinman et al. (2008) sample in order to compare the PPVs of younger (16–23 months old) versus older children (24–30 months old). In this study, all positive screen children were based on parent report and follow-up interview. In the high-risk sample, the

PPV was .79 for the younger children and .74 for the older children. In the low-risk sample, the PPV was .28 for the younger and .61 for the older children.

Although the M-CHAT has been translated in many different languages, the validation of these translations is still pending. Some findings on the Arabic, French, Portuguese, Spanish, Sinhala, and Japanese version have been published (Canal-Bedia et al. 2011; Eldin et al. 2008; Inada et al. 2011; Losapio and Pondé 2008; Perera et al. 2009; Rogé et al. 2009), but these findings were mostly based on small high-risk samples. Two recent published studies form an exception. Inada et al. (2011) reported on the discriminant validity of the Japanese version of the M-CHAT in 1,187 low-risk children of 18 months old, of whom 20 were diagnosed with ASD at age 3. These authors suggest a different cutoff of two or more failed items in total, at which the Se was estimated at .75, the Sp at .89, the PPV at .11, and the NPV at .99. Canal-Bedia et al. (2011) reported on the validity of the Spanish translation of the M-CHAT in two large samples, but the study lacked data on possible missed cases. Therefore, the Se and Sp cannot be estimated (reported Se was 1). The PPVs they reported were .35 for a first sample of 2,480 children, including 63 high-risk children recruited from early intervention service providers, and .19 for a completely unselected sample of 2,055 children.

Item Analysis

In the initial validation study, all but two items discriminated well between children with and children without ASD. Only the item about enjoyment in being swung or bounced on the knee of the parent and the item asking parents if their child can walk cannot distinguish children with and without ASD (Robins et al. 2001b).

Ventola et al. (2007) compared the scores of 195 children who screened positive on the M-CHAT between 16 and 30 months of age and who were subsequently diagnosed with either an ASD, a global developmental delay, or a developmental language disorder. Even when overall language level was controlled for, children with ASD could still be differentiated from children with other developmental disorders, based on their

scores on four items: response to name, declarative pointing, imperative pointing, and following a point.

Reliability

Two studies reported on the internal consistency of the M-CHAT. Robins et al. (2001b) calculated a Cronbach's alpha of .85 for the entire checklist and .83 for the six critical items. These results were replicated by Kleinman et al. (2008). They reported alpha's of .85 and .84, respectively, for the entire checklist and the six critical items.

Inada et al. (2011) looked at the interrater reliability of the Japanese translation of the M-CHAT by comparing the scoring of mothers and fathers of a limited subsample of 24 children. The scoring results of these parent couples were highly correlated: Pearson's $r = .93$. In addition, they looked at the test-retest reliability by asking 22 mothers to fill out the M-CHAT again after on average 8 days. Again, scores on the M-CHAT were highly correlated: Pearson's $r = .99$.

Clinical Uses

The M-CHAT has been available for both research and clinical use since the late 1990s. With the recent recommendations of the American Academy of Pediatrics (AAP) to conduct population-wide screening for ASD at 18 months (AAP 2006), the use of the M-CHAT as a Level I screening instrument for ASD has been recommended by some. However, validation of the M-CHAT is still ongoing and longitudinal follow-up will have to shed light on possible missed cases to enhance the accuracy of the estimates of sensitivity and specificity for the M-CHAT (see also Mawle and Griffiths 2006; Robins and Dumont-Mathieu 2006). Finally, validation of the different translations is still pending.

Based on the current findings, when using the M-CHAT in clinical practice as a Level 1 screening measure, one can expect many false positive screens, especially when used in unselected samples and when the user does not incorporate the follow-up interview in the screening. Therefore, Kleinman et al. (2008) suggested a higher cutoff

for failing when screening in the general population or to combine the use of the M-CHAT as a Level 1 screening instrument with a Level 2 screening instrument or more in-depth parent interview and behavior observation for borderline cases, before a full-scale autism evaluation is instituted.

Different studies used the M-CHAT as a Level 2 screening instrument. For example, Dereu et al. (2012) used the Checklist for Early Signs of Developmental Disorders (CESDD; Dereu et al. 2010) as a Level 1 screening instrument in an unselected sample of 7,092 infants and toddlers attending day-care centers, combined with the M-CHAT as a Level 2 screening instrument for positive screen children on the CESDD or for children at-risk for ASD because of a delayed language development. They compared the M-CHAT with the early screening of autistic traits questionnaire (ESAT) (Dietz et al. 2006; Swinkels et al. 2006) for a referred sample of 197 children between 16 and 30 months old based on the CESDD results and concluded that the discriminant power of these screening instruments for ASD were comparable, although some differences were found in the Se and the Sp of the different instruments. Glascoe et al. (2007) looked at combining a broadband developmental-behavioral screening test as a Level 1 screening instrument, the Parents' Evaluation of Developmental Status (PEDS), with the M-CHAT as a Level 2 screening instrument. These authors advised to base referrals on three or more discrete types of concerns on PEDS, to reduce over-referrals by 70%, while maintaining high levels of sensitivity (81%). However, Pinto-Martin et al. (2008) showed in their study that the PEDS missed the majority of children who screened positive for ASD on the M-CHAT. They concluded that this supports the use of an ASD-specific tool for all children in conjunction with regular standardized developmental screening.

Definition

The Modified Checklist for Autism in Toddlers, Revised – Spanish Cultural Validation is the Spanish version of the M-CHAT-R/F (Robins et al. 2014), a parental report screening questionnaire developed to identify children between 14 and 30 months at risk of autism spectrum disorder (ASD). It is one of the best-known and most

widely used ASD screening tools in the world, because it is concise, easy to administer, and available free of charge on the Internet (<https://mchatscreen.com/mchat-rf/translations/>). It is normally used as a screening tool in the general population (screening level 1) but can also be used to identify signs of ASD in high-risk groups (such as a level 2 screener). The tool consists of a questionnaire with 20 yes/no questions, each of which includes examples to make it easier for parents to understand the questions, and a follow-up interview (FUI) designed to verify the responses of parents who indicate suspected ASD. The questionnaire scoring system establishes three levels of risk according to the number of failed questions. If the questionnaire has two or fewer failed items, it is considered that there is no suspicion of autism; if the questionnaire has eight or more failed items, it is considered that there is a high risk of ASD, and the case should be referred directly for a diagnostic evaluation; finally, if the questionnaire has between three and seven failed items, it is considered that there is a medium risk, and the follow-up interview (FUI) should be administered to clarify with the parents, in a structured way, the failed items of their child. If, after the FUI has been administered, the questionnaire has two or more failed items, the child should be referred for diagnostic evaluation. The FUI can be administered in person or by telephone, and its use is intended to improve the psychometric properties of the tool and limit the costs of the screening program by trying to ensure fewer false positives.

Historical Background

In Spain, interest grew in fostering early detection of autism since the end of the last century, when retrospective studies on early signs became more numerous. Already in the twenty-first century, the first published articles on early detection experiences (Baird et al. 2000; Baron-Cohen et al. 2000; Robins et al. 2001), along with articles on the crucial role of parents in identifying warning signs, studies on factors influencing delayed diagnosis (Coonrod and Stone 2004; Mandell et al. 2002; Mandell et al. 2005), and recommendations

published by several professional organizations and consensus panels recommending systematic screening and early diagnosis (American Academy of Pediatrics Committee on Children with and Disabilities 2001; Filipek et al. 2000; Johnson et al. 2007), prompted interest in adapting a specific tool for early detection of autism in Spain. It is in this context that in 2005 the health authorities of the autonomous region of Castilla y León (Spain) decided to implement a population-based, pilot ASD screening program (for a description of this program, see García Primo et al. (2014)).

The ASD screening program in Spain is administered by primary care pediatricians within the Well Baby Check-up Program, which in Spain is universal and free and includes regular standardized tests that collect data on each child's developmental milestones. From 2005 to 2014, the ASD screening program used the first 23-item M-CHAT questionnaire (Robins et al. 2001) validated and culturally adapted to Spanish by Canal-Bedia et al. (2011). During that 9-year period, more than 9,524 children between 18 and 36 months participated in screening (García Primo et al. 2014).

The Spanish version of M-CHAT has psychometric properties similar to those of the original version, with high sensitivity and specificity, but, like the original version, has high rates of false positives, that is, cases in which the result of the questionnaire recommends referral for a follow-up interview due to suspicion of autism that later turn out not to have an ASD.

In order to streamline the M-CHAT process, The M-CHAT-R/F (Robins et al. 2014) was developed with a focus on reducing false-positive cases without affecting the efficacy of the questionnaire. False positives can be a large hindrance to the health system, especially in the case of diagnosing ASD, as each case needs a lot of time and resources to evaluate. The way the questionnaire is scored was also made easier, thus facilitating its implementation on a populational level.

From 2014 the M-CHAT-R/F Spanish version (Magán-Maganto et al. 2018) has replaced the 23-item M-CHAT and has been implemented in the same region of Spain. Including the Spanish version of the M-CHAT-R/F, a total of 16,149

children in the 14–36-month age range have been screened within the primary health-care system. The inclusion of M-CHAT and M-CHAT-R/F in the Well Baby Check-up Program has facilitated the work of pediatricians in identifying risk signs of ASD, provided a way for families to express concerns about their children's development by responding to the questionnaire, and allowed for coordination between diagnostic services and early intervention services.

Current Knowledge

For the cultural adaptation process, the M-CHAT-R/F was translated and back-translated by two bilingual professionals and compared with the original version. In translating the questionnaire and the FUI, the necessary cultural adaptations were made specially to adjust the examples of each item so that they were clear and understandable in the Spanish cultural context. Several professionals with expertise in child development assessment were also asked to judge the quality of the wording of the questions and examples in Spanish to describe the actions. Finally, 30 randomly selected families filled out the questionnaire to check that there were no significant problems in understanding the questions and examples.

In the validation process, 6,625 children aged between 14 and 36 months were screened. Their parents filled in the questionnaire at the pediatrician's office with their child when they attended for the routine checkup at 18 and 24 months. Also, in some cases, physicians administered the screening protocol before or after these regular visits due to family or professional concerns. The total number of positive cases was 54 (18 failed more than 8 items, indicating high risk; 32 failed 2 or more items after FUI (medium risk); and 4 were referred due to pediatrician concerns). Of those 54 positive cases, 39 (72%) completed the entire assessment protocol. In addition, nine evaluations were administered to children referred for evaluation as possible false negatives. A total of 19 children were diagnosed with ASD (15 true positives and 4 false negatives). The other 24 children who tested positive on the

questionnaire and did not receive a diagnosis of ASD were diagnosed with other disorders or developmental delay and were classified as false positive for ASD. None of the positive screening cases that were evaluated had typical development, suggesting that if the M-CHAT-R/F questionnaire gives a positive result, it is highly likely that the cases require some type of intervention, even if they do not have ASD.

Results of the M-CHAT-R/F Spanish validation were similar to the English version, with sensitivity (Sen) of 0.79, specificity (Spe) of 0.99, positive predictive value (PPV) of 0.39, and negative predictive value (NPV) of 0.99. However, the prevalence was slightly lower in the Spanish sample. Some additional analyses were performed, taking into account the excluded cases (e.g., not answering the phone for the FUI, rejection to attend further assessments, etc.) in order to avoid misrepresentation of the data sample distribution. Estimations of the proportion of cases were made in function of the excluded cases in each stage of the screening procedure. These are the results from the general sample: Sen of 0.86, Spe of 0.99, PPV of 0.41, and NPV of 0.99.

To analyze possible effects of age on the performance of the tool, the psychometrical properties of the M-CHAT-R/F Spanish version were estimated for two different age ranges (14–22 and 23–36 months). For the age range of 14–22 months, the internal consistency was Cronbach's $\alpha = 0.59$ (increasing to a Cronbach's $\alpha = 0.62$ when analyzing the items after FUI); a Sen value of 0.82; a Spe value of 0.99; and a PPV of 0.47. The values for the age range of 23–36 months were the following: Cronbach's $\alpha = 0.63$ (increasing to a Cronbach's $\alpha = 0.72$ after FUI); Sen of 0.75; Spe of 0.99; and PPV of 0.3. Discriminant analyses outcomes were similar in both age strata indicating that the M-CHAT-R/F questionnaire differentiates between ASD, other neurodevelopmental disorders, and language delays and screens negative groups; however the different clusters did have some overlapping with each other.

The results of these analyses showed higher accuracy for the younger age range, supporting the fact that M-CHAT-R/F is a suitable tool for early detection. Although other studies performed

with the original M-CHAT (Sunita and Bilszta 2013; Toh et al. 2018) have demonstrated better outcomes in older ages (24–36 months), there is no certainty as to why this is the case, but possible explanations for this are enhancements of the new version of the tool or in its implementation.

The Spanish validation supported the use of the M-CHAT-R/F as an ASD screening tool on a population level. One of the most important results of this validation was that the number of children that needed a follow-up interview was cut down by 15.1% compared to the old Spanish M-CHAT (Canal-Bedia et al. 2011). This fact provides evidence of the improvement that the new scoring system has given to the health system and affected families.

Professionals collaborating with the Spanish M-CHAT-R/F screening program commented that the combination of a standardized tool and training – focused on red flags of social and communication developmental difficulties at early ages – was key for ASD early detection. The results of the M-CHAT-R/F Spanish cultural validation support the utility of the screening program at a populational level within an NHS and its relevant use in the elaboration of prevention strategies and policies.

Future Directions

Both the original version and the Spanish version of M-CHAT-R/F have succeeded in reducing the number of false positives without this implying that the questionnaire loses psychometric properties (Magán-Maganto et al. 2018), which is an advance in relation to the objective of reducing detection costs. It is a question of reducing not only economic costs but also personal costs. With the use of M-CHAT-R/F, there may be fewer families unnecessarily concerned about unconfirmed suspicion than with previous versions of the same questionnaire. This is a crucial aspect for the development and improvement of universal screening tools that are used even with children with whom neither their parents nor professionals have raised previous concerns about their communicative and social development. From the point of view of personal costs, if a family is

concerned about their child's development, answering the M-CHAT-R/F questionnaire may be a way to resolve their uncertainty. If the questionnaire indicates risk of ASD, the child will be referred for evaluation to confirm or rule out the diagnosis of ASD. In either case, the family will resolve their uncertainty, regardless of whether the case is true or false positive. However, if the family does not have any prior concerns and the questionnaire indicates ASD risk, turning out to be a false-positive case, the use of the screening tool has created an unnecessary concern that did not exist before and that is detrimental. Therefore, the reduction in the number of false positives demonstrated by the validation study of the M-CHAT-R/F Spanish version is a valuable result, because it represents a step in the right direction to support the decision for using this questionnaire in universal screening programs.

Ideally, future versions of M-CHAT-R/F would evolve so that no family would have unnecessary concerns as a result of responding to the questionnaire. Future research should take this need into account, together with the need to reduce the economic costs of an excessive number of unnecessary diagnostic evaluations. That said, progress in reducing false positives should not be based simply on raising the cutoff point (i.e., setting a higher number of failed items to determine the risk of ASD), because that would imply a higher risk of increasing the number of false negatives (Ibañez et al. 2014). The strategy should be aimed at improving the wording of the items to ensure that parents correctly understand the questionnaire questions and that their answers actually represent the child's frequent behavior.

False-negative cases also represent a significant personal cost to families and the child who is excluded from early intervention. The identification of false negatives is also an economic and logistical challenge for any screening program and is key in determining the psychometric properties of a screening tool. In fact, few studies with M-CHAT-R/F have faced the challenge of systematically identifying false negatives and none in the long term. However, in order to know the value of this screening tool, it is necessary to carry out follow-up studies to assess how the cohort of

screening participants has evolved years after responding to M-CHAT-R/F. It is expected that in a few years, as was done with CHAT (Baird et al. 2000) or M-CHAT (Kleinman et al. 2008; Stenberg et al. 2014), some follow-up study on the results of M-CHAT-R/F screening will be published.

Likewise, it is hoped that in the future there will be the possibility to improve the systematization of the follow-up interview process, which should also respond to the purpose of making it easier for parents to better understand the items their child fails and to structure the discussion between the pediatrician and the parents, so that it is possible to share the same vision about the child's behavior and about the risk, sometimes subtle, that the child may be diagnosed with ASD.

In this sense, the M-CHAT-R/F Spanish version could evolve to become the key and initial element of a protocol aimed at facilitating a shared analysis between parents and pediatricians of the child's early communicative and social behavior, at different times of development (Magán-Maganto et al. 2017). The protocol should serve to better organize information and structure parent-pediatrician discussions about concerns related to the child's development. In addition, this approach could be framed in a developmental surveillance perspective in order to systematize information according to different trajectories and key moments of development (18, 24, 36 months, incorporation into kindergarten, preschool, access to primary school, etc.). For example, studies have already suggested that children with an ASD diagnosis and a higher intellectual functioning are detected at later ages when community strains start to be more complex (Christensen et al. 2016; Kleinman et al. 2008).

Modified Testing

Pamela Brucker
Special Education and Reading, Southern
Connecticut State University, New Haven, CT,
USA

Synonyms

[Accommodations](#); [Accommodations in testing](#);
[Modifications](#)

Definition

Modified testing refers to a number of accommodations and modifications that can be made to an instructional assessment to meet a student's individual needs. Common accommodations and modifications include:

- Use of computer or scribe for written response
- Use of augmentative communication device for oral response
- Extended testing time
- Individual or small group administration
- Use of a reader
- Administration in quiet room or space

When testing modifications are determined to be necessary by the Planning and Placement Team, the modifications and accommodations should be identified specifically on the Individual Education Plan (IEP).

Structure

Autism spectrum disorders (ASD) are considered to be among the most heritable of neuropsychiatric disorders, yet the genetic architecture of ASD is complex. Unlike monogenic disorders, which may be characterized by simple Mendelian patterns of autosomal dominant or recessive inheritance, the majority of the cases of idiopathic

autism do not follow such a predictable pattern. For this reason, elucidating the genetic mechanisms of ASD presents a considerable challenge. Our current understanding of the genetic architecture of ASD is that it likely involves the complex interplay of both variants that are rare and common in the general population (discussed in more detail below), together with environmental and epigenetic factors, which are not well understood (Gupta and State 2007; Hoffman and State 2010).

In ASD, modifier genes likely contribute to the complex genetic architecture and to susceptibility. A modifier gene is a gene that influences, or *modifies*, the expression of a second gene. More specifically, a modifier gene does not simply mask the expression of another gene but rather alters the way it is expressed without necessarily preventing its expression. For example, in a monogenic disorder, a modifier gene can interact with the known causative gene so as to influence the severity of the disorder. Therefore, modifier genes contribute to variability in the expression of a particular phenotype such that their interaction with the causative gene can exacerbate or diminish the severity of a clinical presentation (Jorde et al. 2010).

For example, in autism, there are many cases of pedigrees in which two siblings carry a genetic variant that is a known risk factor, yet only one child is affected, or one child has a more severe presentation than the sibling. Such findings, which are inconsistent with predictions based on Mendelian patterns of inheritance, are pervasive in the ASD genetics literature. The term *epistasis* describes the phenomenon of the interaction of modifier and disease-causing genes. Epistasis is likely to be a key factor in disorders characterized by complex genetics, which include not only neuropsychiatric disorders, such as autism, but hypertension, diabetes, and asthma as well. The presence of multiple susceptibility loci has the effect of diminishing the power to identify a causative gene (Cordell 2002).

Function

Our current conceptualization of the genetic architecture of ASD is particularly germane for

understanding the potential role of modifier genes in ASD. For example, it is important to observe that the earliest studies of the genetics of ASD and other psychiatric disorders were based primarily on the common disease-common variant hypothesis, which posits that common alleles, which occur at a frequency of $>5\%$ in the general population, account for the majority of the genetic risk of these disorders (El-Fishawy and State 2010). However, after decades of research, common variation alone was found to account for only a small percentage of the predicted heritability of ASD.

By contrast, the rare variant-common disease hypothesis has been gaining in momentum. Evidence for this hypothesis stems in part from findings of an increased risk of *de novo* variation in ASD in simplex families, as well as the lack of consistent findings from three large, unbiased genome-wide association studies (Anney et al. 2010; Wang et al. 2009; Weiss et al. 2009). In addition, rare variant approaches to candidate gene identification have been clearly pivotal in identifying genes of major effect and highlighting relevant molecular pathways in ASD (Hoffman and State 2010).

Regardless of this conceptual shift, it is likely that both common and rare variant alleles contribute to susceptibility in ASD. Because common variants are associated with relatively modest effect sizes, it is likely that common variants may function as modifier genes in ASD. Rare alleles, such as those that are found to be causative in Mendelian syndromes, have large effect sizes. Therefore, with respect to epistasis, one could imagine that a rare allele could be causative, and its expression could be influenced by common alleles at different loci. However, there is emerging evidence that even some rare variants may carry modest effect sizes and, therefore, may also perform a similar role as a modifier to another rare, causative gene in ASD susceptibility (State 2010; State and Levitt 2011).

Moreover, pleiotropy has emerged as a central theme in the genetic architecture of ASD such that the same genetic mutations can manifest in vastly different clinical phenotypes in different individuals. One explanation for this may be

locus heterogeneity, or variation at multiple genetic loci, which together influence the expression of a known risk factor, and have the potential to result in a range of clinical presentations (State and Levitt 2011). Moreover, it is possible that a combination of rare variants with modest effect sizes and/or common variants at different loci serves as modifying genes in ASD. Therefore, modifier genes likely play a key role in autism and contribute to the varying relationship between genetic mutation and clinical manifestation.

Pathophysiology

One of the challenges of identifying modifier genes and gene interactions that contribute to ASD susceptibility is the need for appreciable power in genome-wide studies intended to identify alleles associated with small effect sizes. An alternate approach taken in some studies is to identify *endophenotypes*, or heritable phenotypes with a presumed genetic etiology. These studies utilize quantitative trait loci (QTLs), which are definable traits that are associated with a particular disorder. The rationale for using QTLs in genetic studies is that it can be used to identify the genetic risk for a particular trait, as opposed to relying on all of the diagnostic criteria for a disorder. Clinical diagnostic categories may be associated with multiple alleles, which complicates the assessment of heritable genetic risk (Abrahams and Geschwind 2008).

Further, the presence of subclinical symptoms in family members of an affected individual argues for the relevance of QTL-based approaches (Abrahams and Geschwind 2008) and suggests that there may be common variants with modest effect sizes that influence phenotype in family members as well. For example, studies have shown that siblings and parents of boys with ASD have quantifiable differences in social responses compared to the general population, suggesting that they share some but not all of the risk alleles that contribute to ASD (Constantino et al. 2006; Virkud et al. 2009).

Multiple QTLs may be defined for ASD, given the range of behaviors associated with this group of disorders. One QTL which was utilized in a study to identify common variants associated with ASD was “age at first word,” in order to identify impairments in language development (Alarcon et al. 2008). The rationale for the use of this QTL in part is that many unaffected siblings of children diagnosed with ASD experience speech and language delay. This study identified a QTL on 7q34-7q36, which falls in *contactin-associated protein-like 2* (Alarcon et al. 2008), a gene that has been strongly implicated in ASD by multiple rare variant studies as well. Therefore, QTLs represent a potentially informative approach to identify susceptibility genes with smaller effect sizes in highly heterogeneous disorders with complex genetic architecture. Moreover, our current conceptualization of the genetic architecture of ASD is that it involves the complex interplay of rare variation, both at the level of the sequence of DNA and the structure of chromosomes, which may function in a causative or modifying manner, depending on the effect size of a particular variant, and common alleles, which have a modifying role, together with environmental factors. At this time, larger genome-wide association studies are needed to obtain the power to identify modifier genes with relatively modest effect sizes.

³Center for Early Intervention Volnickel, Chisinau, Republic of Moldova

Historical Background

Autism in Moldova has a very short history. The story of autism spectrum disorders in Moldova started in 2004, when the first child was diagnosed as childhood autism. However, this is synonymous to autism spectrum disorders (ASD) not existing in Moldova. For many years, especially during the soviet period, children with autism were diagnosed as mentally retarded or some other diagnosis. Most of them had missed the optimal treatment window (early intervention) because of inadequate institutions, insufficient finances, and parental ignorance. Many of the children with autism have been placed into institutions. Because of the poor economic situations and inadequateness of services of social assistance, families were no longer able to care for the medical, physical, and psychological needs of their children and found institutions to be the only viable alternative. This attitudes and approach had lasted for decades in Moldova.

The lack of knowledge on ASD in professionals, who are involved in work with children with autism spectrum disorders (ASD), lack of standardized protocols for diagnosis and

assessment tools, and precarious use of international classifications and diagnostic tools are resulting in low and late detection of autism. Officially in Moldova ICD-10 (1992) diagnostic manual is used, but these days, children with autism spectrum disorders in formal statistics data are getting the diagnosis “mental and behavioral disorders of nonpsychotic character.” So there are no reliable data about the statistics on how many children with ASD are diagnosed in Moldova.

The last years, due the immense influence of nongovernmental organization, supported by Western countries, and the activism of parents associations of children with autism in Moldova, have increased awareness regarding autism in professionals and parents. The organization, “SOS Autism” – one of the most powerful parents associations in Moldova founded in 2008 – is a leader in advocacy of children with ASDs. This organization is lobbying for the development of professional intervention services, inclusive education for children with autism, counseling, informational support, and social assistance for parents raising this children. Today in Moldova, all the burdens related with ASD fall on the shoulders of the parents. In capital city of Moldova, there are several private organizations that offer very expensive ABA – therapy for children with autism. Activities of these companies are not controlled and regulated by the state.

The government published its first autism strategy in 2009. In different regions in Moldova, there have been opened community centers in mental health. But the efficiency of these centers in order to help people with Autism is very low because of lack of professionals working in these centers.

Legal Issues, Mandates for Service

Law no. 60 of 30.03.2012 on the social inclusion of people with disabilities, Chapter IV seeks to provide Education, training, and development of persons with disabilities to participate in all areas of life without discrimination, at the same level with other members of society.

But in reality inclusion of a child with autism in the kindergarten or school depends on parents' education, insistency, and patience. Often parents with higher education are promoters of right approaches toward the children with autism and have a powerful influence in implementations on laws.

Overview of Current Treatments and Centers

The clinic for early intervention in Chisinau is regarded as one of the best clinics working with intervention on kids with ASDs.

SOS Autism – is another clinic in Moldova

Hippo – behavioral intervention center – private center offering ABA sessions

There are somewhere around ten clinics in total in Moldova.

Overview of Research Directions

There is currently no research going on in Moldova.

Overview of Training

Training is in Moldova left to the parents after they have received help in the clinics.

Very few of these kids have personal assistants in school and are left to themselves often.

Social Policy and Current Controversies

Socially, the society is looking down on those with an autism spectrum disorder. They are looked down on, bullied, and regarded as less valuable than children with typical development. Parents often complain that friends push back when they find out that families have a son or a daughter with ASDs. So it is huge social stigma connected to having an ASD diagnosis.

Molindone

Lawrence David Scahill

Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA

Marcus Autism Center, Children’s Healthcare of Atlanta, Atlanta, GA, USA
Department of Pediatrics, Emory University, Atlanta, GA, USA

Synonyms

[Moban](#)

Definition

Molindone is a traditional antipsychotic medication developed for the treatment of schizophrenia. It is more potent than chlorpromazine, but less potent than antipsychotic medications such as haloperidol (► [Antipsychotics: Drugs](#), ► [Haloperidol](#)). Molindone has somewhat unique feature in that it is not associated with weight gain, and, indeed, patients treated with molindone may even lose weight. Molindone has been studied in children but has not been studied in children or adults with autism.

Synonyms

[Flat prosody](#); [Monotonic voice](#)

Definition

Monotone speech refers to a flat prosodic pattern in which the voice varies little in pitch or rhythm. This style of speaking can come across as dry and lacking in affective qualities. Many individuals with autism spectrum disorder use this style of speech, which can make them stand out as “different” in conversational situations and can be an obstacle to forming social relationships.

Monotropism: An Interest-Based Account of Autism

Dinah Murray

National Autistic Taskforce, London, UK

Synonyms

[Attention tunnelling](#); [Ecological model](#); [Resource distribution](#)

Definition

The idea of monotropism makes most sense in terms of a basic model which sees minds as made up of active *interests* shaped by their histories of paying attention in a world (and in an imagined world).

This interest model of mind is ecological, embodied, and exploratory. Instead of applying emotionally charged values to categorize humans, it offers a more objective way of thinking about autistic and other human variations: it does not pathologize them. This is not just semantics, current diagnostic practice stamps “Rejected!” on the core nature of a large part of the human race, with profound repercussions, as history relates if we attend to it.

The model was developed initially as an approach to relevance or salience, so it is about

what matters to a person; it is about what you pay attention to and why. Interests in action retain – are formally changed by – information acquired as they proceed. Homeostasis and reliability of action are pervasive values which are in tension with each other as bodies move through a world viewed through the lens of prior encounters. Thus interests are adaptively informed by their engagement with attractions, emotions, and possibilities.

“Interests” range from fleeting moments to lasting passions; from narrow fixations and self-seeking plots to duties and universal concerns; and *communities of interest* can extend from family and friends, teams, gangs, brands, and nations with long histories to casual folk at bus stops; and from mutual aid to the self-seeking vested interests of corporations and their actors, and the bureaucratic interests of the state.

Interests can be aroused, expressed in the world or the imagination, and informed. Their basic resource is emotional – an energetic force; its quantity as well as its direction and “flavor” tend to incessant change in any individual or set of individuals, against relatively stable patterns of bound energy within a vast network of n-dimensions and gradients, itself a value system.

The will to proceed and take some degree of risk depends on assuming reliable grounds for your actions: all that stuff you do not need to worry about, because it is already settled – sometimes referred to as your “priors” – informs all active interests. Active interests constantly probe at a person’s (or any living being’s) world-engaged edge. They involve having expectations: rough and ready and often disappointed. They can be aroused, informed, expressed/enacted, connected or disconnected, expanded or shrunk, and boosted or undermined. Emotional valences and gradients within an n-dimensional matrix change: possibilities get assessed; certainty is sought; boundaries are created; other goods are sought. Flows and waves and turbulence occur.

The monotropism idea about autism proposes that a leading interest will tend to get a larger share of the scarce resource, which is diverted at boundaries creating channelled flows. The corollary of this larger share can be rich, interest based, inter-connections in some areas, with real gaps in other

areas which may take others by surprise. Flows may also be held back by a significantly higher proportion of resource being assigned to “guard” the boundary relative to a non-monotropic pattern. When a boundary is at its least permeable, patterns which are hard to dislodge will emerge. Cases both of extreme avoidance and extreme attraction are likely and can be problematic as well as rewarding, even for the individual experiencing them.

These patterns of resource distribution can mean virtually undistracted flow versus virtually uncrossable boundaries. The flow states can be immensely satisfying and sometimes highly productive; the barriers can be like cliffs, “frightful, sheer” (Hopkins 1880). It is particularly important to avoid catastrophic events in this “landscape” as far as possible, as they are atypically hard to recover from.

Catastrophes involving sudden loss of capacity (see Thom 1976) may be precipitated by input of any sort: sensory, social, and imaginary; resources may be so scattered and unavailable, and the emotional temper so unsettled that much recovery time is necessary. A high intensity outburst is hard to get over and an inability to send out soothing vibes may get worse all round, if there is no let-up in the pressure. Monotropic people are less likely to have the resources available to repair the ruptured community of interest, therefore it is only fair to ensure they have a chance to get over it. Neurotypicals have to lead on this as they do have the resources, and must avoid projecting assumptions especially negative ones, or may risk causing lasting harm. This can be the downside of so-called “Theory of Mind”: high levels of very unreliable and often pejorative projections of meaning by “typical” people onto others (borderline “gaslighting”) are especially problematic if the others have no means to talk back. In every way possible, the more verbally capable people should gently, with minimum pressure, try to find out more from the inarticulate person and not assume they know best.

The embedding of the all or nothing monotropic disposition, into a very busy environment steeped in uncertainty and egotistical calculation, causes the problems that attract a diagnosis. Like

everybody else, autistic people prefer to operate in a reliable and generally predictable world (see, e.g., Friston 2016). Autistic people’s ability to recover from the impact of unanticipated events which seem harmless to others can be so strongly diminished that a return to capable processing is long delayed. Some of this can be worsened by social pressures from neurotypical people for autistic people to conform. Pushing someone is always the worst, least mutual way to relate to them; doing that while emitting the hostile emotional vibes of the self-righteous can cause the worst possible experience for the socially wary.

Monozygotic (MZ) Twins

Paul El-Fishawy
State Laboratory, Child Study Center, Yale
University, New Haven, CT, USA

Synonyms

[Identical twins](#)

Definition

Twins are two individuals who are the result of the same pregnancy. Monozygotic twins each carry the identical genetic information or deoxyribonucleic acids (DNA).

Monozygotic twins form as follows. When a sperm from the father fuses with an egg from the mother, they form a single cell called a zygote, the earliest stage of an embryo. Further cell divisions occur during embryonic development. At an early point in this development, the embryo can be split into two separate embryos, the cells of each having originated from the initial zygote. Each of these embryos goes on to develop into a separate and complete individual. Since each originated from the same initial cell, each individual is identical in his or her genetic composition. Barring very rare genetic occurrences, since monozygotic

twins share the same genetic material, their physical appearance will be identical, and they will be of the same sex.

In contrast, in the case of dizygotic twins, two separate eggs are released at one time. Each of these is then fertilized by a separate sperm and forms a distinct zygote and embryo. Since each sperm and egg carry distinct genetic material, each of the two embryos will, thus, carry distinct genetic material. On average, dizygotic twins' genetic material is only about 50% identical, as compared to 100% for monozygotic twins. Since each dizygotic twin carries distinct genetic material, his or her physical appearance will be distinct. Dizygotic twins may be of the same sex. However, they might also be of different sexes.

The occurrence of monozygotic twins is rare and more rare, in general, than the occurrence of dizygotic twins. Monozygotic twinning occurs at a rate of approximately 4 in every 1,000 live births worldwide. Monozygotic twins comprise approximately one third of all twins. Two thirds are dizygotic twins. Studies indicate that the rate of monozygotic twinning in the absence of fertility treatments is fairly uniform across different populations around the world. This is in contrast to the uneven ethnic worldwide distribution of dizygotic twinning in the absence of fertility treatments. The rate of both monozygotic and dizygotic twins has increased worldwide since the 1970s. The majority of the increase has resulted from the increase in dizygotic twins born as a result of fertility treatments.

Twin pregnancies of either type increase pregnancy risk and especially the risk of preterm delivery and low birth weight. Approximately 51% of twins are born preterm compared to 9.4% in singletons.

Short Description or Definition

Autism spectrum disorders (ASDs) are a heterogeneous group of neurodevelopmental disorders characterized by impairments in social interaction and communication skills, as well as stereotypic behaviors and restricted activities and interests. Also included within ASDs are conditions which were previously classified as Asperger syndrome (AS) and Pervasive Developmental Disorder-Not Otherwise Specified (PDD-NOS), but now all contained within the diagnosis ASD (DSM-5 2013). Recent studies in Europe and the United States indicate a prevalence of ASD ranging from 1.4 to 212 per 10,000 individuals (CDC 2012; Elsabbagh et al. 2012). Males, compared to females, are circa four times more frequently affected (Rinehart et al. 2002; Williams et al. 2013). The severity specifiers (level 1: requiring support; level 2: requiring substantial support; level 3: requiring very substantial support) may be used to describe succinctly the current symptomatology, with the recognition that severity may vary by context and fluctuate over time (DSM-5 2013).

Recent studies show that more than 70% of all children diagnosed with ASD have at least one and 41% have at least two comorbid psychiatric disorders (Simonoff et al. 2008). In adults with ASD, comorbid psychiatric disorders are common as well. The most common coexisting psychiatric conditions in children and in adults with ASD are intellectual disability, attention-deficit/hyperactivity disorder (ADHD), anxiety disorders, and mood disorders (Geurts et al. 2010). This section will focus on the epidemiology, natural history, prognostic factors, outcomes, clinical expression, pathophysiology, evaluation, differential diagnosis, and treatment of mood disorders in patients with ASD.

Categorization

The term “mood disorder” describes a group of various psychiatric disorders characterized by mood disturbance. According to the DSM-5, this group can be divided into “depressive

disorders” and “bipolar and related disorders.” Depressive disorders include the major depressive disorder, disruptive mood dysregulation disorder, persistent depressive disorder (dysthymia), premenstrual dysphoric disorder, substance/medication-induced depressive disorder, depressive disorder due to another medical condition, other specified depressive disorder, and unspecified depressive disorder. Major depressive disorder (also called major depression, unipolar depression, or clinical depression) is the most common depressive disorder. The disruptive mood dysregulation disorder (DMDD) resulted from the DSM-5 Work Group raised concerns that many youths with severe, nonepisodic irritable mood are inappropriately diagnosed with bipolar disorder. DMDD refers to the presentation of children with persistent irritability and frequent episodes of extreme behavioral dyscontrol which must be present for at least a year. Dysthymia is a condition characterized by a chronic low mood. The unspecified depressive disorder contains any depressive disorder that does not meet criteria for a specific mood disorder. Bipolar disorder is a complex disorder in which the core feature is pathological disturbance in mood ranging from extreme elation or mania to severe depression usually accompanied by disturbances in thinking and behavior, which may include psychotic symptoms. It is an episodic, chronic illness, usually with recovery between episodes. Bipolar disorders include the bipolar I disorder, bipolar II disorder, cyclothymic disorder, substance/medication-induced bipolar and related disorder, bipolar and related disorder due to another medical condition, other specified bipolar and related disorder, and unspecified bipolar and related disorder. The diagnosis bipolar I disorder requires that a person has suffered one or more episodes of mania in their life with or without episodes of depression at other times. Patients with bipolar II disorder experience a milder form of a manic episode, known as a hypomanic episode as well as major depressive episodes. The diagnosis of cyclothymic disorder is given to adults who experience at least 2 years (children: 1 year) of both hypomanic and depressive periods without

ever fulfilling the criteria for an episode of mania, hypomania, or major depression (DSM-5 2013).

Epidemiology

Depressive symptoms are the most common psychiatric concern in patients with ASD and are more likely to occur in adolescence and adulthood. Patients with ASD show a higher risk for developing depressive symptoms compared to the general population (Sterling et al. 2007). Prevalence estimates for any type of co-occurring depressive disorder range from 0.9% to 29% in children and adolescents, which is higher than the prevalence of depression in the general population (Leyfer et al. 2006; Simonoff et al. 2008). Likewise, 77% of outpatient adults with ASD have ever had a diagnosis of depression, compared to 46% of outpatient, non-ASD adults (Joshi et al. 2013). Reported prevalence rates of mood disorders in ASD vary due to differences in study populations, duration of follow-up, and variation in methods (Stewart et al. 2006; Geurts et al. 2010). In addition, autistic symptomatology tends to mask cardinal features of depression and presentation of depressive symptoms might be atypical in patients with ASD, causing a bias in the prevalence rates (Simonoff et al. 2008; Lainhart and Folstein 1994). In study of adults (age 16–60 years) with ASD, the lifetime prevalence rate of depression was 53% and in a younger study population this prevalence ranged from 4% to 38% (Hovander et al. 2009). Leyfer et al. (2006) showed that around 10–15% of children and adolescents (mean age 9) with ASD, ever had depressive symptoms, 10% met criteria for a major depressive disorder, and about 2% met criteria for a depression not otherwise specified. In patients with the former Asperger Syndrome (AS), the prevalence of comorbid depression is reported most frequently with a prevalence of around 30% (Matson and Nebel-Schwalm 2007). Little is known about the prevalence of dysthymia in persons with ASD. Dysthymia is less common compared to depressive disorders (Simonoff et al. 2008). Skokauskas and Frodila (2015) found the

average prevalence of bipolar disorder in persons with ASD to be 7%, with variations between 2% and 31%. It often emerges during adolescence (Vannucchi et al. 2014). Clinical studies on the comorbidity of ASD and bipolar disorder in children are scarce and in particular in the form of case reports. In the following sections, we will focus on the depressive disorder and its symptoms.

Natural History, Prognostic Factors, and Outcomes

Mood disorders are episodic disorders with either a marked change in the context of type of symptoms and variability in intensity of symptoms over time (Leyfer et al. 2006; Matson and Nebel-Schwalm 2007). Due to difficulties in diagnosing a coexisting depression in these patients (see also the sections “Clinical Expression and Pathophysiology” and “Evaluation and Differential Diagnosis”), symptoms are often severe and/or prolonged at time of diagnosis (Skokauskas and Gallagher 2010). Clinical evidence suggests that the outcome of autism might be affected by the presence of coexisting psychiatric disorders in ASD (Ghaziuddin et al. 2002). Especially, depression can have a negative impact on long-term outcome. Effects on a patient and a patient’s family can be wide ranging. Patients with ASD can show a regression of behavioral skills, social withdrawal, and aggressive and oppositional behavior. These changes can interfere with a person’s community participation and his or her social relationships. Furthermore, depression in ASD is associated with poor quality-of-life, inpatient hospitalization, and medical illness (Greenlee et al. 2016; Righi et al. 2017). Depression may also put an autistic patient at risk for catatonia and suicide, especially when symptoms are severe. There are few reports on suicidal behavior among patients with ASD. Causes of underreporting may be the low rate of suicidal behavior among children and preadolescents and the underdiagnosing of ASD in the adult psychiatric setting. Comorbidity is often reported with mood disorders and psychotic disorders, so it is difficult to determine if

suicidality is specifically associated with ASD (Richa et al. 2014).

Clinical Expression and Pathophysiology

Symptoms of ASD and depression show a considerable overlap, which makes it harder to diagnose depressive disorders. Signs of ASD like abnormal speech patterns and social withdrawal might be confused with symptoms of depression such as psychomotor retardation or fatigue. Depressive patients with ASD show a difference in symptom presentation compared to patients without ASD, since expression of depressive symptoms is colored by ASD behavior. Many of these patients are not able to express their feelings, because of difficulties in expressing and communicating emotion due to poor integration between different modalities of nonverbal expressions and insufficient language skills to verbalize changes in feelings and mood (Perry et al. 2001; Stewart et al. 2006; Skokauskas and Gallagher 2010). As in depressed persons without ASD, in depressed patients with ASD one of the main features is a depressed mood. However, in patients with ASD, its presence is more often reported by a patient’s close relative than by self-report (Stewart et al. 2006). This is also the case with behavioral changes, appetite, and sleep disturbance. The majority of patients with ASD and comorbid depression show a decrease in self-care and increased social withdrawal. In youth with ASD, preoccupation with themes of death has also been noted during depressive periods (Ghaziuddin et al. 1995; Perry et al. 2001). When severity of depressive symptoms increases, self-esteem becomes more negative in individuals with ASD. Due to the limited communication skills experienced by many individuals with intellectual disability, symptoms of depression are likely to manifest behaviorally as a regression in adaptive skills and an increase in aggressive and self-injurious behaviors (Magnuson and Constantino 2011; Stewart et al. 2006; Turygin et al. 2013).

With the onset of depression in patients with ASD, both decrease and intensification of autistic symptoms have been reported. Specific

depressive symptoms for individuals with ASD, might be the loss of interest in subject of previous preoccupation and a decline in rigid behavior (Ghaziuddin et al. 2002; Stewart et al. 2006). However, these changes in behavior might be often interpreted as an improvement by their close relatives; in fact, these changes could be a sign of the presence of a depression. Presented symptoms are not always mood-related. The new onset of a depression, for example, is usually associated with a new onset or exacerbation of maladaptive behavior consisting of an increase in aggressive behavior, agitation, irritability, auto-mutilation, compulsive behavior, hypoactivity, or a decline in daily skills (Geurts et al. 2010; Ghaziuddin et al. 2002; Stewart et al. 2006). Especially, self-injury and aggression are often reported. Thus, in all individuals diagnosed with ASD, it is important to investigate whether or not behavior is related to the natural history of ASD, or has changed due to a comorbid disorder. Every ASD patient, especially those with an accompanying intellectual impairment, should be screened for depression if there is a recent history of aggressive outbursts, in the setting of irritability, appetite, and sleep disturbance. In those patients, the most frequent signs of depression are a change in level of functioning; a regression in skills such as incontinence, severe appetite, sleep, and weight disturbance; and the presence of aggression. More unusual features are catatonia and psychotic symptoms (Ghaziuddin et al. 2002).

The exact pathophysiology of depression in patients with ASD remains unclear. Depression is known to be caused by genetic and environmental factors. Children diagnosed with ASD suffering from a depression are more likely to have a family history of mood disorders (Gillberg and Billstedt 2000). Autism and depression seem to cluster in some families, suggesting that in a subgroup of patients, common genetic factors seem to be responsible. However, there is also evidence for an independent genetic origin of these factors (Hallett et al. 2009). The excess of depression in these families does not seem to be related to the stress caused by raising a child with ASD.

Life events play an important role in the onset of depressive symptoms. Psychological processes

such as emotion dysregulation and intolerance of uncertainty have an impact on mood in autistic patients (Hill et al. 2004; Cai et al. 2018). Stressful situations can be overwhelming for patients with ASD, and even to mild life events, they can respond intense. Children with ASD who develop a major depression experienced more negative life events such as family illness, parental divorce, and bereavement (Ghaziuddin et al. 1995). Data on this correlation in adults have not been described yet. Autistic patients might respond with depressive symptoms to negative events because of a genetic predisposition to depression (Ghaziuddin et al. 2002).

Social relationships in patients with ASD seem to be related to the development of depression as well. Interpersonal conflicts with family members have been strongly associated with depressive symptoms in children with autism spectrum disorders. In addition, autistic children with more friendships of poorer quality were found to have the highest levels of depression (Lopata et al. 2010).

Factors affecting the occurrence of depression might be age, level of intelligence, social functioning, and the presence of other psychiatric or other medical disorders. Most cases of depression in patients with ASD have been described in adolescents and adults (Ghaziuddin et al. 2002; Matson and Nebel-Schwalm 2007; Sterling et al. 2007). This could be due to problems of assessment of psychiatric conditions in children with ASD. However, clinical experience suggests that the rate of depression in patients with ASD rises with age (Ghaziuddin et al. 1998; Greenlee et al. 2016). An explanation for this increase with age could be the more pronounced developmental gap between these patients and their same-aged peers and the lack in adaptive skills of executive planning abilities to take necessary steps toward independent living (Sterling et al. 2007). Some researchers have hypothesized that individuals who are higher functioning (e.g., higher verbal capacities, theory of mind, introspective capacities, social strength) may be more likely to experience depression, due to greater awareness of differences and challenges with social interactions (Lerner et al. 2017; Mazurek 2014). Also, higher

functioning autistic adults may be more likely to endorse cognitive symptoms of depression, such as guilty feelings, sense of failure, and pessimism, compared to normal developing individuals (Gotham et al. 2015). It is not clear, however, whether a lack of insight in one's own level of impairment in lower functioning children confers a protection from depressive states. Though, in severe autistic patients with a lower IQ, fewer depressive symptoms were reported (Magnuson and Constantino 2011). Better adaptive skills are associated with increased rates of depression as well.

Evaluation and Differential Diagnosis

As previously described, a coexisting mood disorder in children and adults with ASD can be difficult to diagnose due to impairments in cognitive functions and an overlap in symptoms between different psychiatric conditions. For patients, these impairments make it difficult to describe experiences and mental state. Symptoms are often reported by a patient's close relative instead of by the patient himself/herself. Therefore, it is important to involve the patient's parents and teachers in the diagnostic process. Kanne et al. (2009) found that when using the Achenbach System of Empirically Based Assessment, a higher percentage of parents reported their children as having depressive symptoms than their teachers did. Using the Youth Self-Report form, Hurtig et al. (2009) found strong agreement among adolescent patients with ASD, their parents, and their teachers, indicating awareness of such difficulties.

A mood diagnosis is based on clinical expression of depressive symptoms reported by a patient, its close relatives, and clinician's observation and interpretation. Due to a lack of a "gold standard" diagnostic tool, many different diagnostic instruments have been used for assessment of a depressive disorder in patients with ASD. Traditional measures of diagnosis have, in general, not been tested for validity and reliability in ASD populations. Diagnostic criteria used to identify psychiatric disorders in developmentally disabled

patients may identify only the "tip of the iceberg" (Leyfer et al. 2006). In *children and adolescents*, the Diagnostic Interview for Children and Adolescents, DICA IV, the Child Behavior Checklist CBCL, the Leiter-R-Questionnaires, the Kiddie Schedule for Affective Disorders and Schizophrenia K-SADS-PL, and the Children Depression Inventory CDI (based on the Hamilton Rating Scale for Depression) have been often used. One study used a modification of the Kiddie Schedule for Affective Disorders and Schizophrenia in children and adolescents with autism for the assessment of comorbid psychiatric disorders. They developed additional screening questions and new coding options and found and reported a sensitivity of 100% and a specificity of 93.7% for major depression in their sample (Leyfer et al. 2006). Reiss and Valenti-Hein (1990) developed the Reiss scales for the screening of comorbid psychiatric disorders in children and adolescents with intellectual disability (ID). Results from their study population suggest that these instruments are particularly well suited for screening and for helping in the analysis of the relationships between certain behavior problems and psychopathology in patients with ID (Reiss and Valenti-Hein 1990). In general, observations of behavior and activities are important in the assessment of depression because of their limited verbal abilities and their tendency to express thoughts and feelings through play.

In *adults*, the Beck Depression Inventory (BDI) and the Hamilton Rating Scale for Depression (HRSD) are two of the most widely used scales to assess the severity of depressive symptoms (Stewart et al. 2006). The Beck Depression Inventory, a multiple choice self-report questionnaire containing 21 items relating to symptoms of depression, was found to be an adequate screening instrument for depression in adolescent and adult males with AS (Cederlund et al. 2010). However, even if questions of the BDI and the HRSD have been adapted, some questions may remain difficult for patients with ASD and their relatives. For example, these diagnostic instruments ask patients to rate their mood and if they have feelings of guilt or worthlessness. Therefore, some patients with ASD may not express these feelings

during a depressive episode because these feelings are not in their repertoire (Leyfer et al. 2006; Stewart et al. 2006).

During the lifespan, different problems related to ASD can appear resulting in differences in a person's behavior. To determine whether a person's behavior is due to an underlying autism spectrum disorder or due to a comorbid psychiatric condition, a clinician can assess a patient's developmental history, focusing on the consistency of symptoms over time and pervasivity in different situations. Thus, it will be easier to determine whether a comorbid disorder was already present and if symptoms of comorbidity or ASD are changing (Geurts et al. 2010). As mentioned before, if a change in symptoms of an autistic patient occurs, it is important to screen him or her for comorbid disorders.

The differential diagnosis of mood disorders in patients with ASD is comprehensive because of an atypical presentation of symptoms and includes depressive disorders, bipolar disorders, anxiety disorders, and disruptive disorders. Determined by the presence of episodic manic or hypomanic symptoms, a patient can be diagnosed with a comorbid bipolar I disorder and bipolar II disorder, respectively. When a change of or increase in symptoms is reported in an autistic patient, one should be aware that these symptoms can still exist due to an autism spectrum disorder. An increase in obsessive compulsive behavior can point towards the onset of a depression but be a sign of an obsessive-compulsive disorder as well. Anxiety is often present in patients with ASD, but coexisting anxiety and depressive disorders should be excluded. In school-aged children, a depressive disorder is characterized by agitation and externalizing behavior problems. Therefore, differential diagnostic disruptive disorders have to be considered, such as ADHD and ODD. Psychotic disorders are a part of the differential diagnosis of depression in patients with ASD as well.

Treatment

There is a lack of studies that directly assess the effects of residential programs, treatment

programs, and education programs on depressive symptoms in patients with ASD. However, there are interventions that can reduce mood and related behavioral problems in patients with ASD. Some high-functioning depressive patients with good verbal skills may benefit from psychodynamic psychotherapy. In these cases, a highly structured and directive approach is required. Structured psychotherapy combined with appropriate behavioral and educational interventions are recommended by some studies. In patients with good cognitive capacities and older patients, cognitive behavioral therapy might help them to cope with anger and other depressive symptoms. This therapy is seldom successful without integration and repeating of learned skills in ongoing treatment. Studies in adults with ASD have shown mindfulness-based therapy and social and vocational skills training to be effective for symptoms of depression, but neither intervention has been studied as a treatment for depressive symptoms in children or adolescents with ASD (Spek et al. 2013; Hillier et al. 2011).

The main treatment for depression in patients diagnosed with ASD is pharmacological including selective serotonin reuptake inhibitors (SSRIs), mood stabilizers, antipsychotics, and hypnotics. SSRIs seem to be the most effective drugs in depressive adult patients with ASD (Stewart et al. 2006). These agents are being increasingly used in ASD to control depression and aggression (Ghaziuddin et al. 2002). Serotonin is linked to the mediation of psychological processes such as mood, social interaction, sleep, obsessive-compulsive behaviors, and aggression. Increased rates of platelet serotonin transport and levels of whole blood and platelet serotonin (5-hydroxytryptamine, 5-HT) have been reported in people diagnosed with ASD, and therefore, SSRIs are associated with an improvement of ASD symptoms (Williams et al. 2013). Moreover, treatment in autistic patients with depressive symptoms is in some study populations including children, adolescents, and adults associated with a decrease in low mood, sleep disturbances, and aggressive and self-injurious behavior and an increased capacity for self-care as well (Hollander et al. 2003; Perry et al. 2001; Stewart

et al. 2006). In nondepressed ASD children, low doses of SSRIs (venlafaxine) improved repetitive behaviors, hyperactivity, and communication and language functions (Hollander et al. 2000). However, a Cochrane review found no evidence for the effectiveness of SSRIs as a treatment for children with ASD (Williams et al. 2013). This review focused on the treatment of ASD using SSRIs and did not specifically focus on a coexisting depression.

The Hamilton Rating Scale for Depression (HRSD) is developed to evaluate or report depressive symptoms in nonautistic patients. Since depressive symptoms in patients with ASD show a considerable overlap with these ASD symptoms, but other important signs like increased aggressive behavior are missed, this HRSD is not very sensitive and easy to use in an autistic population. A study by Buchsbaum et al. (2001) reported no significant improvement of depressive symptoms seen in autistic adults treated with SSRIs in depression. However, using the HRSD, some small positive effects of fluoxetine and fluvoxamine on aggressive behavior and anxiety, respectively, in this study population of adults with ASD have been described.

At this time, SSRIs cannot be recommended as a treatment for children with ASD in general. SSRIs are poorly tolerated, and also lack evidence in reducing restricted repetitive behaviors (Goel et al. 2018). Decisions about the use of these agents in depressed patients with ASD should be made on a case by case basis (Williams et al. 2013). Reported side effects of different SSRIs are headaches, sedation, aggressiveness, agitation, and lip dyskinesia by using citalopram. Fluoxetine can cause weight gain and increase agitation, and venlafaxine can cause aggression, nausea, and behavioral activation. Mood stabilizers such as valproate and lithium might improve symptoms related to affective instability and aggression in ASD patients; however, more research is needed on its efficacy (Canitano 2015). The atypical antipsychotic agent risperidone and aripiprazole can improve disruptive behavior in patients with ASD. Tremor, weight gain, and increased appetite are reported adverse effects (Fung et al. 2016;

Hollander et al. 2003). A Cochrane review found that there is limited and inconsistent evidence of the effectiveness of tricyclic antidepressants (TCAs), making clear recommendations impossible at this time (Hurwitz et al. 2012).

Recently, it is hypothesized that the impairment of gut microbiota plays a role in the development of ASD and mood disorders, but the mechanism through which it does is not fully clear. The application of therapeutic modulators of gut microbiota to autism and mood disorders has been experienced only in experimental settings to date, with few but promising results. Well-designed research studies with more participants are needed to provide more evidence that supports the effectiveness of these treatments (Mangiola et al. 2016; Li et al. 2017).

Mood Stabilizers

Lawrence David Scahill

Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA

Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA

Department of Pediatrics, Emory University, Atlanta, GA, USA

Definition

Mood stabilizer is a term used to describe a group of medications that are used in the treatment of bipolar disorder. Currently, mood stabilizers including lithium, valproic acid, and its derivatives, carbamazepine and several antipsychotic medications, are now approved for the treatment of bipolar disorder.

Moral Cognition

Ulrich Max Schaller¹ and Reinhold Rauh²

This chapter is intended to show what is to be understood by the term of moral cognition, as it has evolved throughout history, philosophy, and psychology, how it is connected to autism spectrum disorders, and how novel approaches in moral research can improve knowledge and understanding on relationships between moral cognition and pathogenetic models of ASD.

A glance at the current research literature underlines two topical issues: First, moral research in the field of ASD is still a niche product, and second, while many of the studies suggest a deficit in moral reasoning, only few try to analyze the causes behind these deficits in a way that also considers the content of the presented moral tasks.

Definition

A universally valid and uniform definition of what is meant by the term morality is virtually impossible because of so many different approaches and theories arising from disciplines like philosophy, psychology, and sociology. However, it is undisputed that in most definitions,

morality is described as a regulatory, norm-referenced, and value-oriented system which accrues from cultural and religious experience in the context of a social community and serves as a code of conduct within this very community (Gert 2005; Gert and Gert 2017). From the perspective of an individual, moral is a special type of communication that enables one to express respect or disrespect for a person or an action. It is therefore a binary code of good and evil, respectively, good and bad. The repertoire of moral values arises from conditioning and acquisition of conditions of respect and disrespect (Luhmann 2008).

Concerning the concept of moral cognition, there is also no unequivocal definition. But, most researchers in the field would agree with Greene (2015, p. 40) who states: "... the field of moral cognition does not study a distinctive set of cognitive processes. [...] Instead, it studies a set of psychological phenomena bound together by a common function." And many proponents of this functional characterization would argue that the core function of morality is to promote and sustain cooperation (see, e.g., Greene 2015). This view also entails that there is no specialized "moral organ" (Hauser 2006), but to the contrary "that the 'moral brain' is, more or less, the whole brain, applying its computational powers to problems that we, on non-neuroscientific grounds, identify as 'moral'." (Greene 2015, p. 1013).

Based on this functional characterization of the concept of moral cognition and emphasizing the role of cooperation, it is clear that moral cognition and social cognition and their developmental courses are heavily entwined: The beginning of human life is in stark contrast to the fully expanded potential a human being can develop over lifetime. We are physiologically premature, deficient, and obligatory interdependent (Gehlen 2014; Portmann 1941). Without social bonding, intense care, and dissemination of information, we would be unable to bring into being this potential. Thus, human beings are innately intended to fit into a social and cultural context. Therefore cooperation and pro-social behavior has been an evolutionary advantage and can be seen as behavioral expression of social cognition.

Social cognition can be regarded as a dynamic constructive and conceiving process of

perception, categorization, recall, and evaluation of social stimuli, and it is a prerequisite for moral cognition (Schaafsma et al. 2015). The combination of implicit, automatic, and perceptual categories with explicit categories of attention and experience of agency and concentration has influence on the way we perceive social situations with moral content.

From a psychological point of view, moral or moral behavior can be seen as a function of mind and environmental structures. The objective is that (moral) decisions have to be made in an uncertain world under the constraints of limited knowledge, resources, and time. What is at issue is the match or mismatch of social cognition with the structure of a social environment (Gigerenzer 2010).

The difficulties in communication and social reciprocal interactions, typically associated with a diagnosis of ASD, already indicate that especially the preconditions for normative moral assessments, namely, adequate perception and categorization of social stimuli, do not appear to be available. The result could be altered moral judgments and moral behavior in individuals with ASD.

Historical Background

Since human beings have developed writing, they have registered codes of conduct. Listing, how to behave in a particular situation under certain circumstances, was not only a way to develop a complex progression of rules in terms of social coexistence but also an effective instrument to influence the perceptions, emotions, and intuitions (Haidt and Kesebir 2010) of the society for which those codices were written.

These virtue-based and descriptive considerations of moral were always anchored in a cultural and religious context and reached from classical antiquity to modern times. In the late eighteenth century, moral philosophy tried to separate the code of conduct from cultural and religious influences and the philosophical approaches consider moral either from a deontological or a consequential perspective. The deontological perspective – with its most important representative

Kant (1788/ 2003) – focuses on duties and prohibits actions that don't comply with certain rights and obligations, while the consequential approach focuses on the best possible outcome and judges actions only by their consequences (Bentham 1823/ 2008). Although there were first accounts by Freud (1923/ 2001) and Durkheim (1925/ 1973) for a psychological and sociological perspective on moral, the first empirical attempts were conducted by Piaget (1932/ 1965) and Kohlberg and Kramer (1969) from a developmental perspective: In Piaget's studies on "genetic epistemology," up to 6 year old typically developing children judged the culpability of a person by rather use of the outcome than use of the motive. Kohlberg's method was to interview children, adolescents, and adults about hypothetical moral dilemmas. They investigated moral development by analyzing the answers of the participants explaining their decisions. Based on the resultant narrations, Kohlberg formulated a theory of moral development in the sense of universally ordered stages, including pre-conventional, conventional, and post-conventional moral. However, these rationalistic psychological theories of moral development were heavily criticized and do not have many proponents anymore, whereas some of their methods, especially the presentation of moral dilemmas, were maintained and are still applied in many studies.

The complexity of moral cognition can be illustrated by means of being confronted with moral dilemmas: Participants confronted with a moral dilemma have to deal with many different aspects of social cognition. The common band of all dilemmas is the conflict, respectively, the unsolvability of the given problem associated with antagonistic moral rules, making it impossible not to fail in one of the two options of action.

Current Knowledge

In a commentary on the annual research review of Happé and Frith (2014), Charles A. Nelson III (2014) describes moral as a highly complex behavior. He suggests that high-level social abilities are dependent on more elementary core

social constructs. Furthermore, he argues that many aspects of social development are experience-expectant or experience-dependent.

In his book *A natural history of human morality*, Michael Tomasello (2016) describes the development of human values and norms from an evolutionary perspective. He suggests that development of human morality took place in a two-stage process, whose beginning is marked by the ability to be compassionate and empathetic: The joint intentionality of human beings is based on the principle to project one's self into the other's perspective. Both partners have to know the normative standards of each role. The ability to cooperate and to take joint action allows for a first step of what is called a second-personal morality. The second step in the history of moral development took place 150,000 years ago, following from the enlargement of the social unions and tribes. Within these cultural associations, a collective intentionality developed from the second-personal morality that yielded cultural conventions, norms, and institutions (Searle 1995). This group-related objective morality describes what is seen as good or morally adequate within these cultural associations.

However, a closer consideration of moral reasoning reveals a large number of underlying highly complex processes: The moral content of a social situation has to be perceived and categorized. Actual information content needs to be adjusted on the basis of internalized social norms, own experience, and memory. Various possible courses of action must be balanced against the perceived situation and compared with imagined and anticipated consequences of a possible decision (Beißert and Hasselhorn 2016; Derryberry et al. 2005). Since Beißert and Hasselhorn (2016) have provided evidence that moral development measured with everyday life moral transgression scenarios is not correlated with general intelligence, it must be assumed that processes of moral reasoning follow a different principle.

The spectrum of social context expands with advancing age. Besides other members of the family, this can be kindergarten, school, narrow circle of friends, peer group, and media. The acquisition

of these values and moral rules from the extended social environment develops through imitation and identification (Oerter 1974). Kohlberg and Kramer (1969) also assume that even adolescents and adults process and internalize those values and rules predominantly without undertaking an explicit analysis of meaning and source of these behavior rules. Thus, if the majority of moral impartation takes place by means of expressed emotions, the recipient of moral values must be able to "read" human behaviors (Schaafsma et al. 2015), especially those expressing emotions like respect or contempt.

Being a crucial component of human emotional experience and social interaction, empathy is defined as the ability to share affective states and allows us to predict and understand the feelings, motivations, and actions of others (Bernhardt and Singer 2012). In the range of moral research, there is sufficient evidence that empathy rather than the ability to mindreading is a necessary aspect for adequate moral reasoning (Batson et al. 1983; Haidt and Kesebir 2010; Myrsky et al. 2010).

While Kohlberg represented a rationalistic approach, defined as conviction that explicit and deliberate reasoning is the most important and most reliable way to gain moral knowledge, in the 1980s and especially in the 1990s, many researches began to doubt on rationalism, so that implicit cognitive processes became more and more the focus of scholarly interest in reasoning, judgment, and decision-making in general and in moral cognition in particular. The following current psychological theories of moral cognition have all in common that they emphasize the role of implicit, automatic processes. They differ however with respect (i) to which implicit processes are involved (affective vs. non-affective processes) and (ii) to which degree implicit processes impact moral cognition (exclusive vs. complementary).

At present, the following three psychological theories of moral cognition are discussed: (1) the theory of moral grammar (Hauser 2006; Mikhail 2007); (2) the "social-intuitionist" theory by Haidt (2001); and (3) dual-process accounts, especially the variant put forward by Greene et al. (2001).

The theory of moral grammars assumes an innate and universal set of abstract principles on the one hand and culturally switchable parameters on the other for building specific instances of moral systems (Hauser 2006; Mikhail 2007). Hauser writes (2006, p. 298): “Every newborn child could build a finite but large number of moral systems. When a child builds a particular moral system, it is because the local culture has set the parameters in a particular way. If you are born in Pakistan, your parameters are set in such a way that killing women who cheat on their husbands is not only permissible but obligatory, and the responsibility of family members.” Once the parameters have been set, the grammar automatically and unconsciously generates judgments of right and wrong for an infinite variety of acts and inactions. Therefore, moral judgments don’t depend neither on conscious reasoning, nor on emotions. Instead, moral judgments trigger emotions, which are “downstream, pieces of psychology triggered by an unconscious moral judgment” (Hauser, pp. 30–31). Consequently, emotions are a subsequent process stage resulting from a preceding unconscious and automatic moral grammar module.

The social intuitionist model (SIM) by Jonathan Haidt (2001) emphasizes the role of emotion with recourse to David Hume (1739/2011), who claimed that “reason is the slave of passion.” Consequently, moral cognition is based on an implicit, automatic process (e.g., passion, emotion, or intuition). Furthermore, the degree of emotionality depends on the type of moral dilemmas presented to the participants (Greene et al. 2001; Shenhav and Greene 2014). Conscious reasoning about moral concerns is a subsequent process preceded by (moral) intuitions, being “the sudden appearance in consciousness of a moral judgment, including an affective valence (good-bad, like-dislike), without any conscious awareness of having gone through steps of searching, weighing evidence, or inferring a conclusion” (Haidt 2001, p. 818). Consequently “moral intuitions (including moral emotions) come first and directly cause moral judgments” (Haidt 2001, p. 814).

The dual-process theory for moral decisions of Greene et al. (2001) also operates with the

distinction between cognitive and affective subcategories. Dual-process theories differentiate between fast automatic inferences describable as heuristics and slower, conscious decisions demanding complex computations caused by normative principles such as “thou shall not kill” (Kahneman 2011). Greene et al. (2001) states that the influence of affect on moral judgments depends on given contextual factors that frame the moral dilemma. Depending on the personal emotional involvement, the judgment on the one hand can follow utilitarian approaches if the contextual factors suggest low emotional involvement, and on the other hand the judgment is based on categorical principles if the context indicates high emotional involvement. According to this, moral actions in which the individual is involved very closely and personally might be driven by an emotional and automatic component and as opposed to this actions that are remote and impersonal elicit a rational decision. Greene assumes that conscious and rational decisions are utilitarian and on the contrary a high level of emotionality and participation evokes a more categorical behavior, thus turning Kant upside down and putting him on his feet; in other words, rationality is the basis of utilitarian decisions, and emotional involvement leads to categorical moral decisions and actions.

FMRI studies have shown that moral reasoning correlates with the representation of emotions and intuitions (Reniers et al. 2012) and that the degree of emotionality depends on the type of moral dilemma presented to the participants (Greene et al. 2001; Shenhav and Greene 2014). Nevertheless a meta-analysis of imaging studies, concerning different aspects of moral thought (Bzdok et al. 2012), comes to the conclusion that due to neurotopographical aspects, the neural network of moral decisions is domain-global and can be divided in cognitive as well as affective subsystems.

From a psychological perspective, the task to make a moral judgment can only then be successful if the one who judges is able to empathize with the person on whom the moral judgment has to be imposed (Krahn and Fenton 2009). From an evolutionary point of view, the

ability to moral behavior and moral reasoning can be derived from the interdependence hypothesis (Tomasello 2016): All social species within a social group are mutually dependent regarding their survival. The need of collaborative effort urged early humans to cooperate and thus to consider and anticipate the needs of their counterpart. In order to develop a theory of mind that is able to draw conclusions about emotions, thoughts, and intention of the cooperating partner, especially in complex and dangerous situations, it was necessary to decode and categorize facial expression, gesture, and body posture and to derive an inner state of the counterpart. Consequently, if ToM is necessary for moral reasoning and moral judgment, then individuals with ASD should have difficulties to pass moral judgments in the same way as typically developed individuals.

Kohlberg's approach assumes well-developed language and expressive abilities. Since individuals with ASD have deficits in communication skills (WHO 1993), they can make less use of words describing mental states. Since Takeda et al. (2007) could show significant correlations between moral reasoning and verbal ability in ASD, it is obvious that the linguistic quality of their replies leads to lower scores compared to typically developed peers (Shulman et al. 2012).

Turiel (1983) emphasized the ability to distinguish between moral norms on the one hand and mere social conventional norms on the other. Therefore, he developed tasks, where the display takes the form of pictorial representations, and in addition to the description of those pictorial-presented transgressions, child participants were asked for an evaluation of the seriousness of the transgression. The first use of this task including individuals with ASD showed that children with ASD are able to differentiate between moral and conventional transgressions. Furthermore, there was no correlation between theory of mind abilities (level of ability to solve false belief tasks) and the tendency to differentiate between moral and conventional transgressions (Blair 1996).

Typically developed individuals base their judgments of the moral acceptability of behavior

on their emotional response to that behavior. Brewer et al. (2015) suggest that individuals with ASD do not seem to use emotional information and may rely more on rules to judge moral acceptability. Others tend to explain differences between neurotypically developed individuals and individuals with ASD by analyzing the justifications for a moral decision: While participants with typical development explained their decisions with significantly more abstract rules, participants with ASD tended to nonspecific condemnations of the described behavior to justify their judgment (Shulman et al. 2012).

In their theoretical analysis *Autism, empathy and questions of moral agency*, Krahn and Fenton (2009) propose a distinction between cognitive and affective empathy. Dziobek et al. (2008) showed that individuals with high-functioning autism have access to affective empathy but reveal deficits in cognitive empathy. Based on this evidence, it is to be assumed that there is a capability in ASD to show empathy which is a prerequisite for moral cognition and moral behavior. Suggesting that HFA are capable of moral agency, they encourage to find methods to unfold the term of morality. Based on this evidence, it is to be assumed that there is a capability in ASD to show empathy which is a prerequisite for moral cognition and moral behavior.

A further study focused on the difference between quantitative results and reported personal experience. The results in terms of quantitative analysis suggest that adolescents with ASD demonstrate similar empathetic concern like typically developed peers but have significantly higher personal distress and deviant moral reasoning. In the qualitative survey, adolescents with ASD see themselves as individuals with empathetic concern but without the ability to use these feelings in sociomoral situations (Senland and Higgins-D'Alessandro 2013).

The question of the role of implicit processes in moral reasoning remains open. It is still unclear to what extent empathy and the subsequent moral judgment depend on the social relationships of the protagonists depicted in the moral tasks or dilemmas, respectively what access do

participants with ASD have to such social schemas of relationship. In a study by Patil et al. (2016), hypothetical moral choices were investigated in adults with high-functioning autism, and here again, the role of empathy was the focus of the investigation. The results suggest that adults with ASD are able to differentiate between personal and impersonal dilemmas, they make similar behavioral choices compared to controls, and they exhibit equivalent moral judgments despite deficits in social cognition and emotional processing. Thus again, the claim of Krahn and Fenton (2009) for an unfolding of moral cognition and social cognition in terms of research in ASDs should be addressed.

Although compared to other areas of social cognition the number of studies that survey moral reasoning are few and far between, nevertheless there is evidence that the impairment in understanding others' mind hinders the development of an intent-based moral judgment in children with ASD (Margoni and Surian 2016). People with ASD do not seem to use emotional information and may rely more on rules to judge moral acceptability (Brewer et al. 2015). In the study of Fadda et al. (2016), children with ASD who showed difficulties in perspective-taking, nevertheless were able to take account for the consequences of actions but not for psychological information, in particular the subjective state of an agent in a task, where they should judge the consequences of moral and non-moral actions. Baez et al. (2012) describe a pattern of social cognition deficits characterized by the decreased ability to implicitly encode and integrate contextual information in order to gain access to the social meaning. Comparing moral judgments and the evaluation of those by adults with ASD and neurotypical controls, regarding intentional action of protagonists in moral situations, only subtle differences had been found (Buon et al. 2013). In a qualitative analysis of self-rating the own empathetic concern in sociomoral situations, individuals with ASD envision themselves as empathetic but unable to apply those feelings in moral reasoning conditions (Senland and Higgins-D'Alessandro 2013).

Future Directions

The approaches of Haidt (2001) and Greene et al. (2001) seem to be well suited for appropriate experimental designs to investigate moral cognition of individuals with ASD, especially since the emphasis of their accounts is on emotions. In contrast the application of the moral grammar model by Hauser (2006) appears to be a less researched issue regarding the performance of ASD.

A new approach to unfold morality and emotion is the psychological constructionist account of Cameron et al. (2015). It proceeds from a general correspondence of morality and emotion, emerging from basic cross-domain psychological processes. Perception, memory, emotions, and moral judgments are not separate and isolated entities but emerge from a combination of basic psychological elements that can be combined flexibly and yield different mental states (Barrett and Satpute 2013). The relevant ingredients of this large-scale, domain-general network can always be newly combined, creating a coherent system of functional properties matching with every perceived situation. The interaction of a core affect and conceptualized knowledge in a specific situation leads to discrete emotions and an ensuing judgment of what was perceived. In this context core affect means a physiological state and a non-reflective feeling (Russell 2003), perceptible as valence (positive versus negative) and arousal (high versus low). Important for the process of situative conceptualizing is the transformation of core affect by means of conceptual knowledge comprising general semantic knowledge, autobiographical memories, and situation-specific knowledge (Lindquist 2013). Thus, moral reasoning evoked by moral dilemmata induces a neurophysiological state of valence and arousal, and reconciled with conceptual knowledge, it leads to a moral judgment. A closer look upon the constructionist model of core affect and conceptual knowledge shows that there is an evident congruence with the concept of schemas. The combination of affective states with conceptual knowledge can be understood as a constructionist pattern containing causal representations that

epitomize integrative situational models. Following the definition of Dienstbier et al. (1980), a schema is a “complex of values, attitudes, cognitions, and affective responses that are elicited by and interact with new relevant information. That interaction determines the resultant attributions, decisions, and behaviors” (Dienstbier et al. 1980, p. 194). Schemas represent knowledge of all kinds of content, from ideologies to culture and from behavior in social situations to the meaning of a certain word. Schemas do not only include structural elements but also have a processual component and for this unfold several executive functions (Spada and Mandl 1988, p. 126). Development of social cognition as a prerequisite of moral abilities finds its social world of experience in numberless commonly experienced situations that comprise moral values, attitudes, and the affective disposition of the perceiver, having impact on the development of moral schemas. The development of mindreading is a seminal process including qualitative changes in representational ability (Christensen and Michael 2016), and the construction of integrated situation models requires access to a theory of mind (ToM). Since a schema serves as an implicit (intuitive) automatism to categorize social perceptions, Kintsch and van Dijk (1978) consider schemas as a construction of a framework that integrates information and highlights key relationships in order to provide a model for certain social situations (e.g., moral dilemmas). If so, a person who lacks adequate schemas fails to pick out, structure, and organize the relevant causal factors of a situation and will be unable to understand the context and to predict how the situation will develop.

In order to make such multilayered details of a moral problem present, an investigation of holistic inferential processes, having recourse on social schemas, can show what kind of social schemas are deficient in ASD. Using a schema-theoretical perspective in the field of moral cognition, patients with ASD seem to show a different decision and response behavior, particularly when the dilemmas are based on social schemas involving close social relationships (Schaller et al. 2019).

In order to determine the influence of implicit and explicit processes, moral grammar, and social schemas on moral decision-making in its overall complexity, future studies should develop refined methodological procedures to unfold the factors influencing the process of moral cognition.

More Than Words

Kelly Macy

Department of Communication Sciences, The University of Vermont, Burlington, VT, USA

Definition

More Than Words is a parent-based social-pragmatic intervention program for children with autism spectrum disorders (ASD). It includes education and social support for parents and early language intervention for children with ASD under the age of 5. The program is led by a Hanen-certified speech-language pathologist (SLP) and aims to help parents learn more about communication and, in turn, support their children in increasing their language and communication skills.

Historical Background

The Hanen Centre is a Canadian charitable organization that was founded in 1975 by Ayala Hanen

Manolson to increase knowledge and training of adults to help children become more effective communicators. *More Than Words* was adapted from another Hanen program, *It Takes Two to Talk*, to help meet the needs of parents and their children on the autism spectrum. The parent guidebook was written by Fern Sussman, a speech-language pathologist, and was published in 1999 by the Hanen Centre in Toronto, Ontario (The Hanen Centre 2007).

Rationale or Underlying Theory

The goal of this program is to “empower parents to become the primary facilitator of their child’s communication and language development thereby maximizing the child’s opportunities to develop communication skills in everyday situations” (The Hanen Centre 2007). *More Than Words* reflects a family-centered model of intervention. This program believes that since the parent or caregiver is the most important and constant element in the child’s life, they have an invaluable opportunity to provide consistent interventions in a natural setting to assist their children in experiencing meaningful interactions.

A social-pragmatic theory of language acquisition is the theoretical foundation for *More Than Words*, asserting that the development of communication occurs in the context of the interaction between the child and the important adults in his or her life. Strategies taught in the program are intended to help parents become more responsive to their children’s communication attempts in order to facilitate their language skills. Parents also learn ways to manipulate the environment to increase joint attention and the motivation to communicate.

Goals and Objectives

The *More Than Words* program outlines three main objectives for parents in helping to support their children’s communication skills: parent education, early language intervention, and social support for parents (The Hanen Centre 2007). As part of the parent education component, parents develop a

better understanding of their child’s strengths and challenges by learning about their child’s learning style and sensory preferences. They also learn about basic concepts relating to language and communication and what stage of communication their child is in. This helps them to set goals and recognize communication attempts.

The second objective of *More Than Words* is for parents to carry out early communication and language intervention. The Hanen-certified speech-language pathologist (SLP) works collaboratively with parents to develop goals and implement responsive strategies that can be applied to interactions with their child across a variety of contexts. This is a flexible process and is intended to become a consistent, yet natural part of the day-to-day exchanges between the parent and child. As part of this intervention, parents video-record interactions and strategy implementation with their child. The SLP then reviews the video with the parents and provides feedback to help increase their awareness of their interactions along with the communicative behaviors demonstrated by their child. The SLP facilitates the parents’ metacognitive thinking in the video review to encourage their consistent use of the new strategies.

The third objective is to provide social support for parents, who are at greater risk for fatigue, frustration, depression, and anxiety than parents without a child with developmental disabilities. Support within this context is valuable because it comes from a professional who understands the unique strengths and challenges of their child, as well as from other parents in the group who can empathize and share experiences.

Treatment Participants

More Than Words was designed for parents and their children under the age of 5 with ASD. It can be used with children who are verbal or nonverbal.

Treatment Procedures

The program is led by a Hanen-certified SLP and is offered to groups of up to eight families at one

time. There are three major components of this program. First, there is a preprogram assessment and baseline video recording of an interaction between the parent and child. Next, parents participate in seven sessions of group training, totaling a minimum of 17.5 h. These sessions are led by the SLP and include discussion, PowerPoint presentations, and video clips that aim to help parents learn about early communication and language, how to manipulate the environment to help their child communicate, identify their child's stage of communication, and how to set realistic communication goals. The parents' interactions with their children are video recorded, and three of these recordings are reviewed with the SLP. As part of the video feedback sessions, the parent observes and then describes the strategies they implemented with their child. The SLP probes parent understanding of what was observed and how what a parent did either facilitated or failed to facilitate communication change. The SLP provides coaching to the parents, based on the strategies taught during the parent education sessions. The program is supported by a guidebook, DVD, and PowerPoint slides with video clips.

Efficacy Information

This program seeks to target the communication challenges that are present in children with autism spectrum disorders. The guidebook provides illustrations and step-by-step examples, giving parents a readable and easy to understand resource with opportunities to practice what they learn in the context of everyday activities. Intervention strategies used in this approach, including modeling, reinforcement, and imitation, are commonly used best practices in early education and speech-language therapy and are directly related to the individual child's communication goals. The video-recorded interactions between the child and parent are periodically reviewed by the certified SLP, ensuring that the strategies are implemented in an effective and consistent manner.

Two studies have examined the effectiveness of *More Than Words* for families and children with ASD. The first examined the facilitation of parental understanding of ASD and the social

communication of their children following implementation of the *More Than Words* program (McConachie et al. 2005). Results indicated that parents increased their use of facilitative strategies and children with ASD increased their vocabulary size. A second study found similar results for three families of children 2.8–3.2 years of age with parents increasing their use of responsive strategies and children increasing their vocabulary (Girolametto et al. 2007).

Outcome Measurement

A number of studies provide empirical evidence demonstrating positive outcomes of a social-interactionist intervention for children with ASD (Chapman et al. 1986; Duchan 1989; Mirenda and Dollennan 1986). There is also a recent body of literature that supports this type of intervention being successfully carried out by parents (Aldred et al. 2004; Mahoney and Perales 2003). Two published studies specifically examine the efficacy of *More Than Words*. The first was a controlled trial measuring the effectiveness of parent training on the use of facilitative interaction strategies to enhance the communication skills and behaviors of their children (McConachie et al. 2005). This quasi-experimental study included 26 children and parents in an experimental group and 25 children and parents in a control group. Parents in the experimental group participated in the *More Than Words* training program. The results showed a measureable effect on both the parents' and their children's communication skills. The parents of children diagnosed with ASD showed an increase in responsiveness. The children whose parents attended *More Than Words* had significantly greater vocabulary size than those in the control group, as measured by parental report on the *MacArthur-Bates Communicative Development Inventory (CDI)* (McConachie et al. 2005). The CDI is a frequently used measure of word and gesture comprehension and word and sentence production that is used to assess outcomes following the *More Than Words* program.

Another study examined the social interaction of three preschool children with ASD following

their mothers' participation in *More Than Words* (Girolametto et al. 2007). This was a multiple case study design that aimed to extend the previous study by using microanalytic coding procedures on the recordings of parent–child interactions. The results found that mothers increased their use of spontaneous interaction strategies and their children demonstrated increased vocabulary development and social interaction (Girolametto et al. 2007).

Qualifications of Treatment Providers

The *More Than Words* program is led by a certified speech-language pathologist who has completed a specialized training by the Hanen Centre. First, the SLP needs to be trained in the *It Takes Two to Talk* program. Then, they can complete the 3-day, intensive, small-group training on *More Than Words*, led by a Hanen instructor.

[Startle reflex](#)

Definition

The Moro reflex, also known as the startle reflex, was initially described by the Austrian pediatrician Ernst Moro (1874–1951). It represents one of the infantile reflexes, and it may be observed since birth in all newborns up to 5 months of age. The reflex is triggered when (1) a baby's head falls backward or quickly changes position and/or (2) the baby is startled by an unexpected loud noise. The reflex causes the baby initially to extend the neck and spread out widely the arms and legs (abduction) and then pull the arms back in a clasping motion (adduction). These movements are sometimes associated with cry. The Moro reflex, as well as other infantile reflexes (e.g., the grasping reflex), is considered a residual behavior from when nonhuman primates clung to their mothers swinging through the trees (Thies and Travers 2001).

The absence, persistence, and/or exacerbation of the Moro reflex in childhood and adulthood is generally associated with profound disorders of the motor system (e.g., cerebral palsy). The assessment of the Moro reflex is carried out by pediatricians to evaluate the integration of the central nervous system in early infancy.

As early primitive reflexes, such as the Moro reflex, are gradually extinguished at around 5 months of age, research in this area in the ASD population is very limited. A retrospective study by Teitelbaum et al. (2004) suggested that infants later diagnosed with ASD show abnormal movement patterns that can be interpreted as primitive reflexes “gone astray”; that is, some reflexes are not extinguished at the appropriate age in development, whereas others fail to appear when they should. More empirical research is needed to specifically investigate the development of the Moro reflex in the ASD population.

Morocco and Autism

Ismail El Hailouch

School of Public Health, Child Study Center,
Yale University School of Medicine,
New Haven, CT, USA

Historical Background

As the only country in North Africa that was able to conserve its political stability, Morocco has garnered a stellar reputation amongst foreign investors. The growing interest in the Moroccan kingdom by business leaders has undoubtedly contributed to its economic growth over the past decade, which further embellished the country's reputation. In fact, the country ranked 68th out of 190 nations on the *Doing Business 2017* survey. However, behind the country's growing success lie many striking weaknesses in some of its most vital sectors. Moroccan education, for instance, has been controversial for a long time and remains a focus of political debate. After Morocco's independence in 1956, the country's educational system has been suffering from numerous challenges.

Healthcare is a sector that is unarguably underdeveloped. The quality of care provided and the serious lack of staff and resources are a challenge. There are even more challenges for psychiatric care. While Morocco is ahead of its neighboring countries when it comes to mental health policy, the rules are rarely enforced. The lack of trained providers is another challenge.

The diagnosis and management autism has not been a topic of interest until recently. Autism is considered a “disability” in Morocco and policies and legislation focus more globally on disability than on autism per se.

The main laws that have been issued in Morocco to protect disabled people (including

individuals with autism spectrum disorder) have been the following:

1. Law 92-07 concerning social protection of disabled people – adopted in 1993.
2. Law 03-10 relative to accessibility in addition to a certain number of decrees about the application of laws issued in 2003.
3. Several decrees following the previous laws that urge the applications of laws.

However, despite the activeness of the government in issuing these laws to protect the rights of disabled people, there has not been much improvement made in the field. This reflects the lack of resources to implement the issued laws, the limited emphasis on inclusion of people with disabilities, and issues of lack of acceptance – all factors that contribute to a certain extent to perpetuating disability.

In 2004, a National Disability Survey revealed some quite shocking numbers about the case of disabilities in Morocco.

- One million and a half Moroccan (5.12%) live with a disability, and that on average, a household of four people counts at least one disabled person.
- One out of five disabled people in Morocco never go to a specialized institution.
- Only 1% of disabled people in Morocco benefit from health insurance.
- More than 70% of disabled people don't have any level of instruction.
- The rate of schooling amongst disabled people in Morocco is of only 32.4% as opposed to a 92.6% among the nondisabled.
- 88.6% of disabled people of age above 15 have no professional activity.
- The poverty rate among the disabled is multiple times higher than that amongst the nondisabled.

Since the release of this report in 2004, the government has been active in terms of social protection legislations. Attempts have been made to provide obligatory medical insurance; medical assistance policy and labor legislation has been

enacted. The Moroccan government has acted to protect the rights of people with disabilities and these efforts occur in five main fields: legal capacity, education, institutionalization, women, and disability.

In 2008, the government elaborated the project of law 62-09 which is meant to consolidate the rights of disabled people which have been achieved through a national conference in 2008, followed by four regional meetings. Unfortunately implement of this has been difficult. The adoption of 2011 constitution and through the high orders of King Mohamed 6 has encouraged adoption of this law.

Legal Issues and Mandates for Service

In a recent legislative effort by the Moroccan parliament intended for the protection and advancement of persons with disabilities, an initiative known as the Draft Framework Law or the Draft Law 97.13 was adopted, marking the first legislation addressing the rights of the disabled to be considered by the Moroccan parliament since it ratified the International Treaty on Disability Rights in 2009. Although hopeful for the future of disabled Moroccan citizens, the draft was met with much criticism, particularly from the Human Rights Watch.

Disabled citizens of Morocco have often been treated as objects of charity as opposed to equal citizens, which has inevitably led to an environment of discrimination and stigmatization. Many see this draft law as an opportunity to initiate a large-scale change in the perception of disabilities in Morocco, but as it stands, the Draft Framework Law maintains outmoded perceptions of disabilities and in actuality, places even more restraints on the rights of disabled persons.

Morocco's recent signing of the International Human Rights Treaty, which established the right of disabled persons outlined in the Draft Framework Law as below the international standard, preceded the consideration of the Draft Framework Law. In a letter to the Moroccan parliament, the Human Rights Watch noted the many flaws present in the current Draft Framework law,

among which includes the absence of a clear establishment of the right to education for the disabled due to the segregation of students with special needs with students in regular classrooms, which further amplifies the societal disassociation of disabled persons with the general population. This leads many parents to withdraw special needs students from school. In their letter, the Human Rights Watch demanded proper accommodations in educational settings for special needs students in Morocco. In addition, the general Moroccan population does not adhere to the Draft Framework Law due to a lack of awareness, and certain initiatives should be put in place in order for the law to be as effective as possible.

Current Treatments and Treatment Centers

According to Soumia Amrani, the vice president of Moroccan Collection for Promoting Handicap Rights, resources and treatment centers for disabled persons are readily available in Morocco, but are grossly overpriced and unaffordable for most Moroccan families, especially given the increasing unemployment rate. However, the professional disciplines necessary for the treatment and diagnosis autism are relatively new in Morocco. Starting in the 1980s, and especially after 2000, Moroccan parent-activists have been reaching out to foreign experts in order to change the status quo. They have taken their lead from the Anglo-American Neurocognitive behavioral model of the treatment and diagnosis of autism, rather than the French psychoanalytic one. Moroccan activists have been focusing on raising autism awareness, lobbying government agencies, and establishing the proper infrastructure required for the identification and education of autistic children.

Recently, as part of the National Initiative for Human Development (INDH), King Mohammad VI inaugurated the “Ashourouk” Care Center for Children with Autism, which can enroll up to 100 children, in order to ensure that children with autism and special needs are provided with adequate educational and social integration. The

king noted that among the themes outlined by this initiative was assisting those with special needs in preserving their dignity and preventing them from falling into extreme poverty or isolation. Although much progress has been made in recent years, Morocco lags behind European countries with respect to providing resources a care for autistic children.

Overview of Research Directions

Unfortunately, the majority of ASD research has been conducted in the United States, and this commitment to provide accommodations and understand people with this disorder has not been equally reflected in other countries, such as Morocco. Because of this, parents and families of individuals with autism have been pushed to establish start-up organizations with the sole purpose of providing resources and care for individuals affected with autism. These start-up organizations are working with larger, international organizations in an attempt to advance the understanding of those affected with autism in Morocco. One start-up, in particular the Association Amal pour Enfants aux Benzoints Specifiques Mentaux (A.A.E.B.S.M), was founded by Moroccan activists for disability rights – many of whom had a relative affected by the disorder – and is currently centered in Casablanca. The primary goal of this organization is to provide support for individuals and families affected by ASD by improving public perception and educating the general public about ASD.

Along with local organizations, larger international organizations, such as Autism Speaks, are dedicated to providing care and support for those affected by ASD and have similar objectives to locally run organizations. Autism Speaks has recently began an initiative in Morocco dedicated to providing effective resources to Moroccan individuals and families affected by ASD. However, the incomplete analysis of the resources available in the country has been an obstacle and as a result, Autism Speaks has partnered with students from Worcester Polytechnic Institute in a project designed to collect and analyze data regarding

treatment and education options currently available to autistic children in Rabat, Morocco. The analysis and conclusions of this study will be made available to parents of autistic children in Morocco and will hopefully assist in future projects aimed to advance autism treatment in Morocco.

Overview of Training

Historically, Moroccan psychiatry has been heavily influenced by French psychoanalysis. In the 1980s and 1990s, the very first child psychiatrists in Morocco received specialized training in France, since at the time, there were no training programs for child psychiatry in Morocco. This psychoanalytical approach to psychiatry proved to be ineffective, as many of the children who were treated by these psychiatrists were later admitted into adult psychiatric hospitals. The year 2008 marked a significant advancement in the field of child psychiatry in Morocco, with the opening of two new child psychiatry departments in Casablanca and Salé, pioneering the first child psychiatry training programs in Morocco, which distanced itself from the usual psychoanalytic approach, focusing instead on a biological approach. In fact, over the past couple of decades, Moroccan psychiatry has generally been moving away from psychoanalysis and gearing towards a more biologically based psychiatry.

Major psychiatric hospitals in Morocco have been operating in a style which uses international scientific consensus of the DSM or ICD diagnoses while promoting psychotherapy as well as behavioral and cognitive approaches. In general, the younger generation of psychiatrists in Morocco takes an “eclectic” approach to psychiatry, as many were trained in psychoanalytic theory and as a result see some benefit in thinking psychodynamically; however, they were exposed to neurobiology and pharmacology and believe that cognitive and behavioral therapy play a role in the treatment of mental illness and developmental disorders. They also tend to view the treatment methods of the previous generation of French and Moroccan psychiatrists as damaging and counterproductive.

Mortality

Svend Erik Mouridsen
Child and Adolescent Psychiatry Centre,
Bispebjerg University Hospital, Copenhagen,
Denmark

Definition

The term “autism” is used in this entry to describe all autism spectrum disorders, which include the various types of pervasive developmental disorders according to DSM-IV (American Psychiatric Association [APA] 2000) and ICD-10 (World Health Organization [WHO] 1992).

The life expectancy of people with autism is of interest to parents, health professionals, and service providers concerned with these peoples' lifetime needs. Mortality information that includes the causes of death is important as it can help parents and professionals focus on reducing associated risks and ultimately the rate of mortality among people with autism.

Historical Background

Occasional deaths have been reported in all general follow-up studies of individuals with autism (Ballaban-Gil et al. 1996; Billstedt et al. 2005; Fombonne et al. 1989; Howlin et al. 2004; Kobayashi et al. 1992; Larsen and Mouridsen 1997). Causes of death include traffic accidents (Fombonne et al. 1989; Larsen and Mouridsen 1997); unrecognized volvulus in a woman in a long-term psychiatric institution (Larsen & Mouridsen); status epilepticus (Howlin et al. 2004); and cases of drowning, pneumonia, and complications arising from long-term psychotropic medication (Ballaban-Gil et al. 1996).

However, systematic studies dealing with mortality and causes of death in autism are rare. There are difficulties in obtaining an adequate sample size to calculate specific risks, in studying samples over a suitable time span, and in establishing the cause(s) of death.

Current Knowledge

Standardized mortality ratio (SMR) is frequently used to measure excessive mortality. The SMR is the quotient of the observed to the expected numbers of deaths, and an SMR of 1 indicates that the observed number of deaths is no different from what would be predicted for the general population: An SMR value greater than 1 indicates that the observed mortality exceeds expectations in the group under study.

Only three systematic follow-up studies specifically dealing with mortality and causes of death in individuals with autism have been published so far. Shavelle et al. (2001) and Pickett et al. (2006) reported mortality and causes of death in 13,111 people with autism who were receiving services from the California Department of Developmental Services between 1983 and 2002. The overall SMR was 2.4, indicating a mortality rate more than twice as high as for the general population. The increase in mortality was larger in females than in males. Mortality was associated with mental retardation with an SMR of 3.1 for participants with moderate, severe, or profound retardation, whereas the SMR was 1.4 for individuals with no or only mild mental retardation. Epilepsy was strongly associated with death risk. SMR was 36.9 in participants with epilepsy and moderate, severe, or profound mental retardation against 22.6 in those with no or mild mental retardation. Suffocation (SMR = 51.4 and 5.7, respectively) and drowning (SMR = 13.7 and 3.9, respectively) were also noted to be frequent specific causes of death and, like epilepsy, associated with the level of cognitive impairment. Similar results were obtained in a Danish study (Isager et al. 1999; Mouridsen et al. 2008) in which an overall SMR of 1.9 was reported in a nationwide cohort of 341 individuals with autism (average age 43 years) observed between 1960 and 2007. Again, the SMR was particularly high in females. Epilepsy (SMR = 35.0) and infectious diseases were among the most common causes of death. Epilepsy was notably marked in deceased females; five of the eight deceased females had epilepsy. Different kinds of infectious diseases (meningitis,

pneumonia, appendicitis) were associated with death in seven individuals. In a Swedish community-based study of 120 individuals with autism, mean age 33.2 years, Gillberg et al. (2010) found an overall SMR of 5.6. They also noted that the mortality rate was particularly high in females. Associated medical diseases (including epilepsy with cognitive impairment) and accidents accounted for most of the observed causes of deaths.

Prevention efforts to decrease mortality in people with autism need to address the conditions that are the immediate causes of death (i.e., infectious diseases, epilepsy, and accidents). However, the behavioral characteristics that define autism often make care difficult and can lead to exacerbations in the state of somatic illness or diagnostic delay, eventually leading to death-causing illness (Larsen and Mouridsen 1997; Mouridsen et al. 2008). Assessing pain and discomfort in a cognitively impaired, nonverbal patient is difficult, and of paramount importance is the involvement of the parent(s) or other care providers, if available. The best pain assessment by proxy is that provided by caregivers or family members who know the patient well. Only they can identify changes from a patient's base line behavior that may signify pain and discomfort. Patients may be uncooperative or combative if they do not understand the need for help. It is important to realize that many people with autism react badly to any change in their environment, and therefore, a visit to a general practice or a hospital can be very alarming for them, in particular, if an unplanned acute hospital admission is necessary (Scarpinato et al. 2010; Souders et al. 2002). In some patients, conventional peri- and postoperative management is impossible and alternative strategies are needed (Dell et al. 2008; Van Der Walt and Moran 2001). Likewise, venipunctures, intravenous insertions, and initiation or change of medical treatment can be difficult to carry through. It is also noteworthy that Williams et al. (2000) found that 62% of parents reported difficulty giving medication to their children with autism.

An association between autism and epilepsy has been consistently reported, and the literature

presents a wide range of co-occurrence estimates from 5% to 46% (Spence and Schneider 2009). These authors also report that more severe intellectual disability is associated with greater rates of epilepsy. Considering the high prevalence of epilepsy in autism, it is therefore important to suspect the comorbidity of epilepsy in every individual presenting with autism. It follows that understanding the needs of this group is particularly important within any major epilepsy service. Since epilepsy is strongly associated with death risk, careful monitoring of anticonvulsant treatment is essential in those individuals with a concomitant occurrence of autism and epilepsy. However, the clinical identification of seizures may be difficult in some cases. The diagnosis of partial complex seizures, in particular, can be complicated by the presence of atypical body movements and behavioral patterns often seen in association with autism (Bauman 2010). Obtaining a high-quality EEG can also be difficult, and effective communication usually has to be through a caregiver.

Since accidents are often avoidable, special attention should be paid to the safety of community surroundings. In the Mouridsen et al. (2008) study, two participants, who both lived in specialized institutions for autistic people, managed to swallow dangerous objects and choke on them during an unsupervised period. According to the standards of the caregivers, the two patients should never be left unsupervised.

As the rates of autism diagnoses increase (Rutter 2005), it becomes more and more imperative for health care providers in any setting – family, institutions, and primary or acute care – to understand the unique challenges of people with autism. The findings published so far underscore the importance of maintaining sufficient competence levels in the fields of internal medicine and neurology within the autism care system to recognize and properly manage somatic as well as neurological diseases. As there is little information about the best practice for providing care to people with autism in institutional or hospital settings, it is important to develop nursing standards that address care for people with autism.

Future Directions

To conclude, mortality is increased in people with autism, and individuals with diminished cognitive functioning or epilepsy are at particularly high risk of a reduction in life expectancy. However, increased understanding of the most common causes of death can help parents and other caregivers focus on reducing risk and, ultimately, the rate of mortality among people with autism.

Motivating Operation

Amanda P. Laprime

The Center for Children with Special Needs,
Glastonbury, CT, USA

University of Rochester Medical Center,
Rochester, NY, USA

Definition

Motivating operations (MO) is a general term to describe antecedent events which momentarily alter the effects of a reinforcing or punishing consequence, and therefore alter the future frequency of behavior related to that consequence. Motivating operations alter the effectiveness of reinforcers and punishers in two ways, which designates different classifications of MOs.

Establishing operations (EO) increase the effectiveness of a consequence (see ► [“Establishing Operations”](#)), and abolishing operations (AO) decrease the reinforcing or punishing effectiveness (see ► [“Abolishing Operations”](#)) (Laraway et al. 2003). The term MO is important because it refers to “not only how much someone wants something, but how hard they will work to get it” (Langthorne and McGill 2009, p. 22).

Historical Background

Establishing operation was a term originally coined by Keller and Schoenfeld (1950) to describe a series of motivational events and their effect on behavior. Since, the designation, conceptualization, and distinctions of MOs have evolved considerably.

Moving from the term Establishing Operation to Motivating Operation: Researchers in the field of behavior found that the term *EO* was limited as it only included events resulting in the relative increase in the effectiveness of a consequence; discarding those variables which decreased the value of a consequence. While the inherent limitations to this term were recognized (Michael 1982, 1993, 2000), it was deemed cumbersome to have different terms to describe each operation. More recently, there has been a push to utilize the general term, *MO*, and distinguish between EOs and AOs based on their relative effects on consequences and behavior (Laraway et al. 2003). For the remainder of this entry, *EO* will describe only variables that increase the reinforcer/punisher effectiveness, *AO* will denote only events resulting in the decreased reinforcer/punisher effectiveness, and *MO* will denote the general class of variables that alter the effectiveness of such consequences.

The designations are important due to the essential role that all MOs, including both EOs and AOs, have on the understanding of human behavior. The current conceptualization of MOs has been found to be important in the role of reinforcing or punishing consequences for behavior. Importantly, interventions to address challenging behavior and skill deficits in individuals

with autism spectrum disorders (ASD) have benefited from an analysis of motivating operations as an independent variable.

Role in operant conditioning: Historically, operant behavior has been conceptualized as a three-term contingency (Antecedent-Behavior-Consequence), in which a stimulus readily evokes a behavior because of a past history of reinforcement in the presence of that stimulus. The conceptualization of MOs added a variable that provides an explanation for momentary differences of such operants (Sundberg 1993). The importance of the MO cannot be understated. Motivation is paramount to understanding behavior. Although all operant behavior occurs due to its history with reinforcing or punishing consequences, the probability of such behavior being emitted is dependent on the relative effectiveness of such consequences. Specifically, if a reinforcer is more effective due to an EO, behavior will be more likely to be emitted at that time. If, in contrast, there is an AO in effect, the same behavior would be less likely to occur. In its simplest form, motivation can be described by its biological basis in states of deprivation or satiation. More complexly, motivation can come under the control of arbitrary relationships due to conditioning paradigms. Regardless of etiology, the analysis of the MO provides the conceptual foundation for why a reinforcer is effective for a person, at any moment in time (McGill 1999).

Conditioned motivating operations: A series of papers by Michael (e.g., 1982, 1993, 2000) distinguished between MOs that are unconditioned and those that are conditioned. Unconditioned MOs, or UMOs, are those events that change the effectiveness of a reinforcer or punisher with no learning history (e.g., food deprivation, sleep deprivation), while conditioned MOs, or CMOs, are those that are learned. Three distinct CMOs have been classified based on the process by which this learning occurs: the reflexive conditioned motivating operation (CMO-R), the transitive conditioned motivating operation (CMO-T), and the surrogate conditioned motivating operation (CMO-S). Each of these alter the value of some other stimulus, such that its presentation is momentarily establishing or abolishing.

The CMO-S refers to a previously neutral stimulus that has been correlated with another MO, and therefore acquires the same effects on behaviors and consequences as the original MO. The CMO-T refers to motivational events that establish another stimulus as a reinforcer. The CMO-R refers to motivational events which signal an improving or worsening set of conditions, therefore altering its own removal as a type of reinforcement or punishment (Langthorne and McGill 2009). Although complex, a conceptual understanding of these CMOs has enhanced intervention around challenging behavior and teaching language skills to individuals with ASD.

Distinguishing between different antecedent events: Motivating operations have often been confused with other antecedent variables, such as discriminative stimuli (S^D s, see ► [“Stimulus Control”](#)). The important distinction is that while S^D s signal the availability of reinforcement or punishment for a response, MOs increase or decrease the relative value of a reinforcer or punisher as a consequence for that response. This value altering effect (Laraway et al. 2003) results in a relative increase or decrease in the probability of a behavior occurring at that moment, rather than the consistency of responding under similar conditions in the future. In an applied example, a water fountain signals the availability of reinforcement for stopping and drinking (i.e., S^D) but whether you stop and drink depends on whether you are thirsty in the moment. Thirst, a noted state of deprivation, is an unconditioned EO for water as a reinforcer.

Current Knowledge

The concept of the MO is influential for any intervention that relies on reinforcement or punishment for its effect. Without an understanding of the MO, one cannot truly understand the impact of an intervention, as well as the variables in play if one is not working. For example, if a reinforcement program is put into place to increase academic behavior, it is paramount that the child is motivated for the reinforcer (i.e., there is an EO in place). Motivation for a reinforcer in this situation

may be one component of an effective intervention. Conversely, if in the previous example the child is not motivated for the reinforcer, academic work behavior may not increase, and the intervention may be deemed ineffective. This would be an error in the analysis, as in this situation, reinforcer saliency may be impeding progress. This same analysis applies to any situation in which the development of adaptive behaviors, or the omission of challenging behavior is contingent on delivery of a reinforcer. Most prominently, the MO has been highlighted in the areas of verbal behavior, decreasing challenging behavior, and skill acquisition instruction.

Verbal behavior: Motivating operations have been instrumental to providing a full account of language development and the acquisition of skills related to language (see ► [“Analysis of Verbal Behavior \(AVB\)”](#)). A thorough analysis of language development is pertinent for learners with ASD who may have deficits in basic communication skills. To illustrate, the concept of the MO is paramount for teaching mands, otherwise known as requests. Skinner (1957) described the “mand” as reliant on a salient EO as an antecedent condition. Meaning, requesting only occurs in the presence of motivation for something and is specifically reinforced by access to that which was requested. For example, requesting for food items will only occur when someone is hungry (a noted EO, state of deprivation). The specific reinforcer for this request would be food. “Mand training” is a particularly popular and important skill acquisition program for early learners with ASD. Requesting for items is dependent on motivation for that item or activity. Meaning, if a child is not motivated for the cookie, they are not going to independently ask for the cookie, regardless of whether they have the skill in their repertoire or not. This analysis is important in understanding how to teach these types of language skills. Sweeney-Kerwin et al. (2007) implemented a procedure to teach requesting to children with ASD. Importantly, their participants were dependent on seeing the things they were requesting which is inconsistent with the way in which requesting typically evolves. The importance of motivation was a critical component of the intervention as it

was necessary that the individuals were able to request for things, only when there was motivation in place. By manipulating aspects of the EO, the intervention was successful in teaching individuals with ASD to request for the things they wanted, without needing to see them in the environment. This type of requesting is paramount to the development of a requesting repertoire that is independent and generalizes across a variety of variables.

Similarly, the CMO-T has been used to support teaching the skill of asking for information (Hall and Sundberg 1987; Sundberg et al. 2002). In these interventions, individuals were taught to seek out information. Importantly, information had to become momentarily valuable for the questions to occur. An analysis of the CMO-T was pertinent in establishing motivation for information. This was done by repeatedly presenting individuals with preferred items in containers. Then, the instructor removed the items from the containers. Since the individuals had previously experienced the container and the item together, the presentation of the container without the item resulted in motivation for information about the location of the item, evoking the questions of “Where is the item?” This study effectively increased “question asking” as a skill for individuals with ASD who previously did not inquire for information. Without this careful analysis and application of CMOs, it is unlikely that the skill of asking for questions would have developed and persisted for learners with deficits in this complex area of language development.

Challenging behavior: The concept of the MO has implications in the area of challenging behavior as well. Many individuals with ASD engage in challenging behavior that impacts their access to a variety of environments and experiences (See ► “Challenging Behavior”). Literature on functional assessment (See ► “Functional Behavior Assessment; ► Functional Analysis”) has suggested that MOs play a primary role in the understanding of challenging behavior and its functional relationship to environmental events. A series of studies on functional analyses have shown that the presence or absence of MOs have directly influenced the relative success with

understanding the environmental variables related to challenging behavior during behavioral assessments (Call et al. 2004; Iwata et al. 1994). Similarly, MOs have been integral to interventions intended to decrease challenging behaviors in individuals with ASD (Smith and Iwata 1997). Motivation as an independent variable has been shown to impact the efficacy of behavior reduction procedures for stereotypy (Lang et al. 2009), destructive behavior (McComas et al. 2003), aggression (McGuinnis et al. 2010), self-injury (McComas et al. 2003), and noncompliance (Call et al. 2004). One example of this has been conceptualized in the literature on the CMO-R. Carbone and colleagues (2010) discussed the role of the CMO-R as it relates to problem behavior during discrete trial instruction (DTI; see ► “Lovaas Approach”). Specifically, this line of work has provided a conceptual analysis for the conditions during DTI which may establish instruction as aversive, and some practical modifications for reducing said aversiveness, resulting in a decrease in challenging behavior. Another important example relates to a common consequence for challenging behavior time-out. Removal from an environment, contingent on a challenging behavior, is intended to punish or decrease the future frequency of the challenging behavior. Unless there is motivation (i.e., an EO) for the time-in environment, it is unlikely that the time-out procedure, will suppress or decrease challenging behavior. This analysis of motivation is pertinent in understanding the mechanisms responsible for successful interventions.

Skill acquisition: The concept of the MO has also been employed to enhance skill acquisition instruction for individuals with ASD. Several instructional strategies have been identified as AOs to decrease escape-maintained behaviors during work and increase appropriate participation (Carbone 2013). For example, fast-paced instruction (Roxburgh and Carbone 2012), modified task difficulty (McComas, Thompson, implementing choice options (McComas et al. 2000), and the high probability (high-p) request sequence (Mace et al. 1988) have all been demonstrated to increase compliance during instruction by abolishing the aversive value of demands.

In addition, a series of studies have shown that contriving MOs during instruction can enhance repertoires such as engagement (Neely et al. 2013), play skills (Lang et al. 2010), discrimination (Lotfizadeh et al. 2012), eye contact (Carbone et al. 2013), social initiations (Taylor et al. 2005), and joint attention (Dube et al. 2004; Isaksen and Holth 2009). For example, Lang and colleagues (2010) found that when an AO for stereotypy was created prior to play sessions, children with ASD were more likely to engage in functional play with their peers during subsequent play sessions. Taylor et al. (2005) manipulated an establishing operation to increase social interactions for children with ASD. Here, the authors contrived motivations for a reinforcer that a peer was in control of and taught the participants to request for the items from their peers. The results of the study demonstrated that only when there was motivation for the item would the children request from their peers. Additionally, the authors reported that outside of the study, the children who participated were observed to request across other peers. One child requested in an untrained situation and in a novel environment as well. These data suggest the importance of motivation when planning for instruction with learners with ASD.

Future Directions

An understanding of MOs has been demonstrated to increase the efficacy of interventions, understand more fully behavioral presentation, and enhance the overall acquisition of necessary skills for individuals with ASD. Continued research and application of interventions based in the conceptualization of MOs are necessary to expand the analysis of behavior as it relates to these areas.

Definition

An important body of research relates to interventions that improve motivation in children with autism. This literature has been particularly relevant, as individuals with autism often appear unmotivated to engage in social and learning interactions. It has been hypothesized that a lack of motivation to engage in social and learning interactions may be caused by external variables (see below). Therefore, environmental manipulations should be effective in changing the response-reinforcer relationships that led to the development of these motivational deficits. Along those lines, a number of studies have focused on identifying specific variables that effectively improve motivation in children with autism. To start, child-driven approaches, such as providing the child with the choice of stimulus materials, activities, and conversational topics, have been shown to improve responding and attention (Koegel et al. 1987). This has also been referred to in the literature as “following the child’s lead,” and its effectiveness has been well documented in regard to improving a range of behaviors such as communication, academics (Koegel et al. 2010), and socialization (Koegel et al. 1987). Such approaches have been compared and contrasted with previous empirically

based approaches that focus on an adult-driven curriculum without any input or consideration of the child with autism's changing reinforcer hierarchy and have been shown to be more effective.

Another variable that improves motivation to respond is the interspersal of new (acquisition) tasks that the child has not yet mastered with previously mastered (maintenance) tasks (Dunlap 1984; Koegel and Koegel 1986). Rather than repeatedly presenting new target tasks that are likely to be difficult, interspersing maintenance tasks with acquisition tasks results in increased correct responding in addition to improved overall responsiveness. Similarly, when tasks are varied frequently, rather than being taught in a drill-like context, motivation improves (Dunlap and Koegel 1980). Another body of research relates to the manipulation of consequences for child responses. As opposed to using a strict shaping paradigm that only rewards responses that are as good or better than the previous response, child motivation can be improved by rewarding child's attempts to respond correctly that are free of disruptive or repetitive behaviors (Koegel and Egel 1979; Koegel et al. 1988). Related to this, providing direct and natural rewards, which are inherently linked to the child's response, results in improved motivation in terms of more rapid acquisition of the target behaviors (Koegel and Williams 1980; Williams et al. 1981). That is, rather than providing an arbitrary unrelated reward (e.g., food item or token) contingent upon a correct response, the child is provided with rewards that are directly related to their behaviors. For example, a food may be given to a child learning first words contingent upon labeling the food item so that it is directly related to the child's response. The aforementioned procedures can be used in combination with one another and have been documented to improve motivation as measured by decreased levels of disruptive behavior; improved performance in academic, language, and social domains; and improved child affect (Koegel et al. 1987; Koegel and Koegel 2006). Another variable that has been shown to affect child motivation for some (but not all) children is clinician affect. For example, research suggests that some children respond more

favorably when the clinician shows specific types of affect while providing reinforcers, such as either strong positive affect or low affect depending on the child. As a whole, these studies suggest that motivation appears to be measurable and treatable. At this point, the most effective programs use a combination of motivational procedures, applied simultaneously, to produce large changes in the behavior of children with autism. This body of literature has led researchers to conceptualize the construct of motivation as "pivotal" such that positive changes in a number of untreated symptoms/behaviors occur when a child with autism is motivated to respond (Koegel and Koegel 2006). Thus, the literature on pivotal response treatment (PRT) uses motivational procedures as a core underlying principle of the intervention, and motivational components have effectively been incorporated into interventions for improving articulation (Koegel et al. 1998), first words (Koegel et al. 1987), academic engagement (Koegel et al. 2010), and social conversation (Koegel et al. 1987) in children with autism. Additionally, studies have shown that collateral improvements in disruptive behavior occur when such motivational variables are employed without needing to target the disruptive behavior directly. While the general concept of motivation can be conceptualized by feelings of an individual, such as the desire or incentive to engage in activities, motivation also can be defined by observable and measureable behaviors. Specifically, motivation has been measured by task engagement, responsiveness, decreases in response latency, initiations, and affect, as well as an absence of avoidance behavior (Koegel et al. 2001). During the intervention sessions when motivational procedures are incorporated into the teaching, the children show an increase in the number of responses and decrease in response latency, initiate new related behaviors, and demonstrate positive affect. Task engagement and responsiveness can be monitored by the number or rate of responses the child emits. Latency can be measured by assessing the amount of time that passes before the child begins to engage in a learning task or activity. Initiations are important in that if the children are motivated to engage in

the tasks, they are likely to spontaneously engage in the task, sustain participation, and initiate future activities. This also relates to generalization, as motivated children may spontaneously demonstrate the targeted responses across settings, behaviors, and people. Changes in affect can also be seen in motivated children. Affect is often rated by Likert scales in general categories of positive, neutral, and negative affect and has been defined as interest (e.g., child is alert and involved in the activity), happiness (e.g., the child smiles, laughs, and seems to be enjoying self), and enthusiasm (Baker et al. 1998; Koegel and Egel 1979; Koegel et al. 2009). In addition to child affect, motivation can be measured by lowered levels of disruptive behaviors (Dunlap and Koegel 1980; Koegel et al. 1992). Multiple measures showing improved latency, affect, happiness, enthusiasm, and levels of disruptive behavior have been used to measure motivation with high degrees of reliability (Dunlap and Koegel 1980).

Historical Background

The interest in the construct of motivation, as it relates to autism spectrum disorder (ASD), came about as a result of the apparent lethargy and disinterest individuals with autism may demonstrate in regard to social conversation, learning, and other activities (Lovaas 1977). This led researchers to hypothesize theories for this lack of motivation. A possible theoretical explanation is related to the concept of “learned helplessness.” Specifically, it has been hypothesized that during exposure to an uncontrollable outcome, a lack of contingency between the behavior and the outcome is learned (Seligman and Altenor 1980). Simply put, if an individual receives noncontingent rewards or punishers, the individual will not initiate behaviors and will appear lethargic and inactive. Early animal studies that postulated the learned helplessness theory were carefully controlled and showed the effect of uncontrollable events causing a disruption in behavior. Specifically, the once responsive animals became unresponsive and lethargic. Subsequently, studies replicated this phenomenon using human

subjects in controlled settings. They showed that if individuals’ responses were not reinforced, they too simply stopped responding (Gatchel et al. 1975). Learned helplessness has also been hypothesized to occur in other human conditions, such as stress and depression (Miller and Seligman 1975; Price et al. 1978). Some studies have also shown that physiological changes, such as norepinephrine depletion, weight loss, and ulcers occur at a higher rate when consequences are noncontingent and outcomes are uncontrollable (Abramson et al. 1978; Seligman and Weiss 1980). Data also suggest that this theory may be highly relevant for autism as well (Koegel and Egel 1979; Koegel and Koegel 2006).

The theory of motivation is an important concept in regard to intervention for autism, as it supports the notion that some, or all, of the disability may relate to environmental variables. That is, the state of an apparent lack of motivation is hypothesized to occur when the individual’s responses are uncontrollable, or “learned helplessness.” In regard to children with autism, reduced social responding that begins very early in life due to central nervous system dysfunction may result in the children experiencing high degrees of noncontingent consequences. This may create a situation wherein the child learns that responding and reinforcement are independent. This weakening of the response-reinforcer relationship may cause a decrease in social responding and lower levels of motivation in children with autism.

Current Knowledge

The lack of responsiveness and long response latencies demonstrated by children with autism as well as an apparent lack of motivation and curiosity have been discussed since the 1960s when principles of applied behavior analysis were beginning to show promise with children with autism. Within the broad framework of environmentally manipulated behaviors, researchers discussed the role of reinforcers in this apparent lack of motivation. They proposed that the potency or availability of reinforcers may not be

adequate when a child with autism engages in difficult tasks (Koegel and Egel 1979), thereby creating a lack of motivation. Koegel and Egel (1979) were the first authors to present the possibility of learned helplessness and the importance of motivation to address the problem. Following that publication, a number of studies addressed individual areas of intervention that appeared to directly improve motivation. In 1987, Koegel, O'Dell, and Koegel published work using an intervention package, containing a large number of motivational variables (discussed above), was especially effective.

Future Directions

Although the literature describes specific procedures for improving motivation, there continues to be a need for future research relating to the measurement of motivation, the refinement of existing procedures that improve motivation, and additional intervention procedures for improving motivation.

Motivation Assessment Scale

Corey Ray-Subramanian

MAS

Description

The Motivation Assessment Scale (MAS) is a rating scale that assesses functions of problem behavior in individuals with developmental disabilities through informant responses. It includes 16 questions and is comprised of four subscales that each represents a possible function of the behavior: attention, escape, sensory, and tangible. Each question has six response options (0 = never, 1 = almost never, 2 = seldom, 3 = half the time, 4 = usually, 5 = almost always, and 6 = always). Scores are calculated by summing the item ratings within a particular subscale/function and calculating the mean rating for that subscale. High scores for one or more of the subscales suggest that those functions may be maintaining the individual's problem behavior (Durand and Crimmins 1988), although the authors of the instrument do not specify what constitutes a high score. An example item on the MAS is "*Does this behavior occur when you are talking to other persons in the room?*" (Durand & Crimmins, p. 102). The MAS is considered an indirect assessment method because it is removed in time and place from the behaviors being measured (Floyd et al. 2005).

Historical Background

The MAS was originally developed to assess the functions of self-injurious behavior, in particular (Durand and Crimmins 1988), within a framework of applied behavior analysis. It was

designed to be a more efficient alternative to direct functional behavior analysis methods (Durand and Crimmins 1988). Based on previous literature identifying common functions of self-injurious behavior (i.e., social attention, tangible consequences, escape from unpleasant situations, and sensory consequences), Durand and Crimmins (1988) created four subscales, each representing a specific function, that comprise the MAS. The items were generated following interviews with teachers, clinicians, and parents of children with developmental disabilities.

Psychometric Data

In their original study based on 50 children with developmental disabilities who exhibited frequent self-injurious behavior, Durand and Crimmins (1988) reported interrater reliability coefficients ranging from .66 to .92 for the individual items and .80 to .95 for the raw mean subscale scores. Test-retest reliability, over a 30-day period, was calculated and the coefficients ranged from .89 to .98 for the individual items and .92 to .98 for the mean subscale raw scores. The authors also found that teachers' ratings on the MAS were highly predictive of student's behavior in an analogue experimental condition (Durand & Crimmins).

However, the psychometric properties of the MAS have since been questioned by other researchers (e.g., Paclawskyj et al. 2001), as subsequent studies examining the validity and reliability of the measure have produced inconsistent results. It has also been argued that research on the MAS and other indirect functional assessment measures has not carefully examined validity evidence based on scale content and informant response processes, evidence of user satisfaction with the measure, or the treatment utility of the scale (Floyd et al. 2005).

Some factor analytic research has provided support for the intended four-factor structure of the MAS (i.e., sensory, escape, attention, and tangible), although the factor structure was somewhat different for a sample with lower frequency problem behaviors (Singh et al. 1993). Other researchers have not found support for the four-

factor model, specifically the sensory function subscale (Kearney et al. 2006). Joosten and Bundy (2008) also failed to find support for the construct validity of the MAS in the form of a four-factor structure or as a unidimensional measure of motivating factors for stereotyped behavior. In addition, Duker and Sigafoos (1998) results did not fully support the factor structure of the MAS, and their results suggest that the type of problem behavior may be differentially related to reliability and factor structure.

Research examining the internal consistency of the MAS has also produced inconsistent results. Cronbach's alpha coefficients for the subscales ranged from .68 to .86 in a study by Sreat and Connelly (1996) and .68 to .87 in a study by Duker and Sigafoos (1998). However, Shogren and Rojahn (2003) reported values ranging from .80 to .96.

Subsequent research on the interrater reliability of the rating scale has produced lower values than those reported in the original Durand and Crimmins (1988) study. Shogren and Rojahn (2003) found interrater reliability coefficients for the four subscales ranging from .35 to .73, and Sreat and Connelly (1996) reported values ranging from .31 to .57. Another study found that interrater agreement depended upon the type of problem behavior (Duker and Sigafoos 1998). For example, raters were less likely to agree on the functions of destructive behaviors (e.g., aggressive behavior) as compared to maladaptive (e.g., self-injurious behavior) and disruptive (e.g., screaming) behaviors (Duker & Sigafoos).

Research examining other types of reliability evidence for the MAS has also failed to provide clear evidence that the instrument is psychometrically sound. For example, Shogren and Rojahn (2003) reported test-retest reliability coefficients ranging from .71 to .89 for the four subscales, which are lower values than those reported originally by Durand and Crimmins (1988). Sreat and Connelly (1996) also found evidence of poor reliability in the difference scores between subscales, which are used to make clinical decisions regarding the function of the problematic target behavior.

Clinical Uses

The MAS has been used clinically to identify possible factors that are maintaining an individual's problem behavior. The identified function can then be used to develop an intervention program to reduce the problem behavior and to select reinforcers for appropriate behavior. Some have argued that the MAS should be used in conjunction with direct observation methods because of its psychometric limitations (e.g., Duker and Sigafoos 1998; Shogren and Rojahn 2003; Sreat and Connelly 1996).

Motor Control

Su Mei Lee
Child Neuroscience Lab, Yale Child Study
Center, New Haven, CT, USA

Synonyms

[Cerebellum](#); [Motor cortex](#)

Definition

Motor control refers to the coordination of information exchanged between the neocortex in the brain and the muscular and somatosensory systems to bring about controlled, or voluntary, movements. Controlled movements are planned, organized, and initiated in the prefrontal, premotor, and primary motor cortices. Instructions for the movement are then sent through the spinal cord to the appropriate muscles to execute the movement. The somatosensory system provides feedback about the movement, and the basal ganglia, brain stem, and cerebellum fine-tune the movement by adjusting force and correcting for movement errors.

Motor Planning

Casey Zampella and Loisa Bennetto
Department of Clinical and Social Sciences in
Psychology, University of Rochester, Rochester,
NY, USA

Definition

Motor planning can be broadly defined as the capacity to plan the necessary steps to achieve purposeful movements. It is often considered under the larger concept of praxis, which comprises the conceptualization, organization, and execution of an action sequence. Although the terms “motor planning” and “praxis” are sometimes used interchangeably, motor planning may be more accurately thought of as one element of praxis, distinct from both the idea behind the movement and its actual implementation. In addition to being dependent in part on neural motor systems, motor planning may be affected by the multimodal integration of sensory processes involved in proprioception, vestibular functioning, and vision, and by capabilities for preemptively formulating a mental sequence of actions.

The clinical assessment of motor planning typically occurs as part of a broader evaluation of motor functioning. Few clinical tests specifically measure motor planning; however, a number of standardized instruments can provide relevant information. These include batteries that assess a range of motor abilities, such as fine and gross motor skills, limb and verbal praxis, and sensorimotor functioning. In addition, the assessment of adaptive skills and motor performance during everyday activities can provide some indication of motor planning ability. A thorough developmental history is also usually conducted for children with motor planning or praxis difficulties, including the documentation of major motor milestones and early motor behaviors.

Disorders related to motor planning and praxis include apraxia and dyspraxia. Apraxia is typically thought of as an acquired neurological condition in which skilled movement is impaired in the presence of intact basic sensorimotor and attentional functioning. The term “dyspraxia” is often used to describe similar symptoms that are present early in development and have a less concrete etiology. Deficits in praxis in autism spectrum disorder (ASD) generally fall under the category of dyspraxia or developmental dyspraxia. Disorders of praxis can affect multiple modalities, including fine motor functioning, gross motor functioning, oculomotor control, orofacial movement, and speech production.

Historical Background

General impairments in motor functioning have been documented in individuals with ASD since both Kanner’s and Asperger’s initial descriptions of the conditions. Since then, basic motor deficits have been consistently found in ASD, with many individuals displaying abnormalities in gait, postural control, coordination, balance, tone, and/or strength. Furthermore, there is evidence that aspects of motor dysfunction are often identifiable early in development, present throughout the lifespan, and pervasive across levels of cognitive functioning.

The study of praxis has been an area of increasing interest within the larger domain of motor

functioning in ASD. One focus of earlier work related to praxis was the assessment of clumsiness, or motor incoordination, as a possible symptom to differentiate subtypes within the autism spectrum. Historically, clumsiness was often considered a particular characteristic of Asperger syndrome, whereas individuals with classic autism were thought to have preserved motor function. Most evidence now suggests that motor clumsiness does not discriminate among subtypes; individuals with both Asperger syndrome and autism show similar degrees of impairment. Although clumsiness and dyspraxia are sometimes used synonymously, it is important to recognize that clumsiness is a clinical description that does not address the specific nature of an underlying motor impairment. Current research has taken a more systematic and componential approach to studying dyspraxia, with the goal of identifying the precise roots of the movement disturbances seen in individuals with ASD.

Current Knowledge

Dyspraxia in ASD

The growing body of literature focused on dyspraxia in ASD has, on the whole, confirmed that both children and adults with ASD display deficits on overall measures of praxis. In fact, difficulties with skilled limb movements have become one of the more reliable motor findings in the field. Impairments have been found in the ability to produce actions in response to command, imitate actions, and carry out actions involving tools. Moreover, these impairments are seen in transitive movements, or those involving objects, as well as intransitive movements, which do not include objects and are often more symbolic. Although basic motor skills are associated with praxis ability, individuals with ASD consistently appear to display deficits in praxis beyond what can be accounted for by general motor dysfunction. This suggests that praxis is a specific area of weakness for individuals with ASD within the larger motor domain. In addition, although correlations between praxis and both age and cognitive ability have been reported, the

available data largely indicate that symptoms of dyspraxia in ASD remain even after controlling for these factors. Of particular interest, praxis impairment has been shown to predict the severity of autistic symptoms, whereas correlations between basic motor skill and ASD symptomatology have not been found.

Motor Planning in ASD

Research has also sought to examine the motor planning component of praxis more directly. One approach has utilized paradigms in which potential impairments at the planning or preparation stage of a goal-directed motor act can be assessed separately from impairments at the execution stage. An example is a task in which participants are required to generate hand movements toward alternating targets. The planning stage is defined as the time between the appearance of the target and the point at which the hand begins to move; the execution stage is defined as the time in which the hand is in motion. Research employing these types of tasks has found that the planning stage of movement is generally atypical in individuals with ASD, while the execution stage is similar to typically developing controls.

Motor planning abilities in individuals with ASD have also been investigated using a reach, grasp, and place paradigm, in which participants are instructed to reach for an object, pick it up, and place it in a specified location or orientation. In one study in which children were required to reach, grasp, and place a rod in a certain position, typically developing children consistently chose initial movements that allowed for a comfortable end state. In contrast, children with ASD were more likely to favor an easier initial grip, even when this forced an uncomfortable final hand posture. In a similar study, children were asked to pick up an object and place it in either a small or large container. Typically developing children took longer during both the reach/grasp and place stages on the trials with the smaller compared to the larger target container. This suggests global planning of actions, such that when the final step of a motor act requires more precision, the execution of earlier steps is also affected. In contrast, for children with ASD, only the place

stage was longer, signifying that although they were affected by the increased precision required at the end, they were less likely to plan for this in their initial actions.

Overall, the performance of individuals with ASD on reach, grasp, and place tasks indicates that they are less likely than typically developing individuals to plan goal-directed actions holistically. Instead, they seem to execute the necessary steps for a motor act independently, such that knowledge of the end goal does not influence the initial movements in an action sequence. However, there is some evidence to suggest that the motor planning behavior of children with ASD may not differ from their peers when tasks have fewer higher order cognitive demands. For example, on a more constrained grip selection paradigm in which children reached for and grasped a handle and turned it in a specified direction, differences in performance were not found between age-matched groups.

Related research has found that some individuals with ASD may have difficulty with coordinating the stages of a reach-to-grasp movement, failing to temporally couple the velocity of the reach stage with the timing of their hand opening during the grasp stage. One study found that lower functioning children with ASD did not seem to synchronize the timing of their reach and grasp based on target location and size in the same way as controls. Instead, they performed the movement in two distinct stages, completing the reaching movement first, and then opening their hand to grip the object. However, high-functioning children with ASD performed similarly to typically developing children, with the timing of the reach and handgrip movements well synchronized.

A final area of research on motor planning in ASD has explored how the advanced presentation of information about a target affects goal-oriented movements. One hypothesis is that goal-directed actions are planned in a predictable sequence, where the appropriate hand is chosen first, followed by the direction of the movement, then by the amount of movement necessary to achieve the target. This model has been tested through the use of a precue technique, in which prior information about hand, direction, and/or movement

extent is given to the participant. Results indicate that young adults with and without ASD display a similar, predictable pattern on this task, suggesting that they can effectively use advanced information to plan movements. Individuals in both groups tend to derive the most benefit from information pertaining to which hand to use, followed by information about direction, and finally by information about the amount of movement. Nevertheless, the reaction times of individuals with ASD were slower and more variable than those of their peers.

Clinical Significance

Motor deficits are not a diagnostic characteristic of ASD, yet the importance of studying how various aspects of motor dysfunction may contribute to the condition has been increasingly recognized. Without a doubt, impairments in planning purposeful movement can have deleterious effects on many aspects of daily functioning, including basic tasks like feeding and dressing. In addition, the impact of difficulties with motor planning on social and communicative functioning is a topic of growing interest. Some theories posit that the motor system plays a foundational role in certain interpersonal skills. The ability to effectively plan and produce movements within an appropriate time frame may be crucial for reciprocal social interaction. In addition, praxis ability has been empirically associated with imitation. Difficulties with imitation have been widely documented in ASD across ages and functioning levels: individuals with ASD have been shown to imitate less than their peers, display poorer approximations of imitated movements, and consistently make specific types of errors during imitation tasks. Furthermore, abnormalities have been found for the imitation of nonmeaningful movements, as well as movements with more social or symbolic significance, suggesting that a fundamental problem with skilled motor functioning may be involved in imitation impairments in ASD.

Future Directions

The extant research has established motor planning as an area worthy of further investigation in ASD.

An important direction for future research will be to build on existing work exploring components of motor acts to identify the specific aspects of goal-directed movement that are affected in ASD, both globally and at different points in development. There is also a need for further research on how functioning in other domains may impact the components of movement. Although basic motor functioning, general intellectual ability, attentional skills, motor learning, and sensory abilities have all been implicated in the organization of movement, the relationship between these various skill domains and motor planning in individuals with ASD is still not well understood.

Recent work has specifically highlighted the need to distinguish between motor planning and higher order planning, the latter of which is thought to rely on executive functioning skills. Motor planning is distinctly dependent on the ability to implement learned movements, whereas executive planning requires abstraction and mental sequencing of goal-oriented decisions. Both motor and executive planning are often necessary to effectively prepare and execute actions, making it difficult to pin down the precise nature of movement planning difficulties in ASD. One viewpoint has been that individuals with ASD perform poorly on motor planning tasks because of executive functioning impairments, and that they would demonstrate intact performance on tasks that do not require executive skills. However, at least one study has shown that individuals with ASD perform poorly across a range of motor planning tasks regardless of the level of executive demand, suggesting that motor planning may be impaired even in situations that do not require higher order abilities.

Another direction for future research is continued exploration of the neurobiological underpinnings of motor planning and related functions in ASD. Although research in ASD has implicated abnormalities in a number of regions important in motor functioning, less work has specifically addressed functional atypicalities during motor tasks. The neurobiology of the motor system in typically developing individuals is well understood. Thus, studying the neural bases of motor dysfunction in ASD may offer a more straightforward avenue for identifying structural and

connectivity abnormalities in this disorder, potentially leading to a better understanding of the neural bases of other affected domains. In addition, functional neuroimaging studies can provide further information on how individuals with ASD approach motor planning tasks, helping to answer questions about the degree to which executive and other skills play a role in motor planning in this condition.

Finally, further research is needed to better understand if and how motor planning difficulties might influence the pathogenesis of core symptoms in ASD, including social and communication impairments. The answers to these questions will benefit from more research on the developmental timeframe of motor planning in ASD, and how this interfaces with other aspects of development.

Description

The *Movement Assessment Battery for Children, Second Edition* (MABC-2) (Henderson et al. 2007) is a revision of the *Movement Assessment Battery for Children* (MABC) (Henderson and Sugden 1992) and is one of the most widely used assessment tools by occupational therapists, physiotherapists, psychologists, and educational professionals (Barnett and Henderson 1998; Brown and Lalor 2009; Wiart and Darrah 2001). The purpose of the MABC-2 is the identification and description of impairments in children’s motor function. It is composed of two parts: the Performance Test and the Checklist (see Table 1). The Psychometrics Centre at the Cambridge Judge Business School (n.d.) states that the MABC-2 Performance Test or the Checklist “can be used to identify a child with motor difficulties by comparing the child’s score to the normative data. However, neither instrument should be used on its own as a predictive screening instrument” (para 1).

The MABC-2 Performance Test involves children completing a series of fine and gross motor

Movement Assessment Battery for Children: Second Edition (MABC-2), Table 1 Movement Assessment Battery for Children, Second Edition (MABC-2; Henderson et al. 2007) summary of Performance Test and Checklist data

Test section	MABC-2 performance test	MABC-2 checklist
Purpose	The identification and screening of children with delay or impairment of their motor development, provision of appropriate intervention planning, clinical exploration, program evaluation, and as a research tool with children who are believed to be at risk of motor difficulties	The efficient and economical assessment of the movement competence of children and to identify children who are likely to have difficulty with their movement. The MABC-2 checklist takes assessment into the everyday situations in which the child has to function, including the extent to which a child's attitudes and feelings about motor tasks are situation specific or more generalized. Therapists can also obtain parents' or teachers' views on a child's movement in everyday settings
Test age range	3:0–16:11 years across three age bands (AB) <i>AB1</i> 3:0–6:11 years <i>AB2</i> 7:0–10:11 years <i>AB3</i> 11:0–16:11 years	5:0–12:11 years
Who can administer?	Individuals who are certified by a professional organization recognized by Pearson assessment or who have a graduate and/or postgraduate qualification relevant to their profession. This qualification code would include psychologists, speech therapists, physiotherapists, occupational therapists, mental health professionals, health practitioners, and education professionals. No additional specialized training is required; however, familiarity with test items is required. It is envisaged in the future that specialized training modules will be set up to allow a wider range of professionals' access to the MABC-2	Available to psychologists, classroom teachers, special education teachers, physical education specialists, pediatricians, occupational therapists, speech therapists, and physiotherapists. A child's parent or primary caregiver may also contribute to the completion of MABC-2 checklist if requested by a professional
Time to administer	Individual administration usually takes approximately 20–40 min depending on the age of the children; however, 50 min is suggested for setup, testing, and completion of the record form	The MABC-2 checklist can be completed with a group or individual and takes the respondent approximately 10 min to complete
Time to score	10–15 min	10 min
Materials/equipment required	Stopwatch, clipboard, pencil, correct age band record form, test manual, and test kit containing full set of testing materials and manipulatives	Checklist and pencil
Method of administration	Physical demonstration of all items is required to ensure each child assessed fully understands the verbal instructions for each task. Verbal instructions are not scripted, allowing for the assessor to alter their language according to the age of the child and the child's level of comprehension. Important features of the physical demonstration are emphasized verbally to the child. The child is provided a practice phase (that is not scored/rated) and a formal trial (which is scored/rated)	A basic list of specific motor behaviors is outlined for the adult rater to observe and rate the child's performance and competency. A total score is obtained by summing the ratings, and this is then mapped onto a "traffic light" scoring system (outlined below under the "scores provided" heading)

(continued)

Movement Assessment Battery for Children: Second Edition (MABC-2), Table 1 (continued)

Test section	MABC-2 performance test		MABC-2 checklist
Response format	The child's performance on a task can be recorded in 1 of 4 ways		In sections A and B, the rater has four alternative responses for the child's task competence
	1	The child's best result for an individual task *	0 – very well 2 – almost
	2	An "F" is recorded for a failed attempt	1 – just OK 3 – not close
	3	An "R" is recorded for refusal to attempt or complete a task	The summed score of sections A and B represents the total motor score and interpreted with the "traffic light" system outlined below. Section C allows for either a yes or no response to factors that may affect a child's movement and is not meant to be summed. Rather, these factors should be reviewed by the assessor to determine how much the child is prevented from demonstrating their true capability due to the influence of the observed factors
	4	An "I" is recorded if it is inappropriate for a child to attempt a task	
	* if a child completes a task successfully according to the item parameters, the item is scored according to criteria and then converted to a scaled score reported as 1–5, where 5 indicates a poor performance. Some items are scored based on number of correct repetitions, length of time, or accuracy of responses		
Scale construction/ test structure	Eight tasks are administered across three specific components: (a) manual dexterity, (b) aiming and catching, and (c) balance. Adding all eight scores yields a total motor impairment score (maximum 40). Overall scores that are below the 15th percentile are deemed <i>at risk</i> ; those below the 5th percentile indicate a <i>definite movement impairment</i>		The checklist comprises three sections
			<i>Section A:</i> 15 items regarding movement in a static or predictable environment
			<i>Section B:</i> 15 items regarding movement in a dynamic or unpredictable environment
			<i>Section C:</i> 13 items regarding non-motor factors that may affect movement
Standardization sample	The norms of the MABC-2 are derived from a stratified sample of 1172 children (48.3% male, 51.7% female) in the United Kingdom (UK), who were assessed between November 2005 and July 2006. This sample closely approximated the UK 2001 census data. The test sample included 12 UK geographic regions, 16 age levels (e.g., ages 3–16 years), four ethnic groups (e.g., white, 90.2%; black, 2.6%; Asian, 3.9%; and other, 3.2%), and five levels of parental education		656 children of the 1172 sample fell into the age range of the MABC-2 checklist. Of the 656, teachers for 395 children (50.9% male, 49.1% female) completed the MABC-2 checklist. The test sample included 12 UK geographic regions, 8 age levels (e.g., ages 5–12 years), four ethnic groups (e.g., white, 90.4%; black, 2.6%; Asian, 3.5%; and other, 3.5%), and five levels of parental education. This sample closely approximated the UK 2001 census data
Scores provided	Standard scores and percentile ranks are provided. "Total standard scores are calculated and converted into percentiles to determine how a child's motor coordination compares to typically developing children of the same age" (Camden et al. 2013, p. 1). Additional score interpretation according to a "traffic light" system is provided. This system is the same for both the MABC-2 performance test and checklist, allowing for direct comparison if required. Any child whose score falls at or below the 5th percentile is regarded as having a <i>significant movement difficulty</i> (red zone), between the 6th and 15th percentile <i>at risk</i> (amber zone), and above the 16th percentile as unlikely to have a movement difficulty (green zone)		A percentile cut score is provided. The "traffic light" system shows whether a child is in the "green zone" which is within the age-expected normal range, in the "amber zone" indicating a need for monitoring due to minor delay or movement problem, or in the red zone where it is highly likely that child has a serious movement problem

tasks on which they are scored and rated. The Performance Test is designed for use with children aged 3–17 years in one of three age bands (AB) (AB1, 3:0–6:11 years; AB2, 7:0–10:11 years; and AB3, 11:0–16:11 years) and evaluates motor skills under three categories: (1) Manual Dexterity, (2) Aiming and Catching, and (3) Balance.

The MABC-2 Checklist requires an adult who knows the children being assessed well to rate their motor competence on a 30-item scale. Since the MABC-2 is a revision of an existing instrument, it is important for professionals who use the motor skill battery to be familiar with its age range, scoring format, standardization sample, reliability, validity, and clinical utility. Details of the purpose, age range, administration, response format, scale construction, standardization, and scores provided of the MABC-2's Performance Test and Checklist are reported in Table 1.

The MABC (Henderson and Sugden 1992) was normed with children from Canada, the United States, and the United Kingdom and has subsequently been translated into several European languages (including Swedish, Danish, Dutch, Italian, and Finnish) (Livesey et al. 2007) and Chinese (Chow and Henderson 2003). Predominantly used throughout the United Kingdom, Canada, Australia, several European countries (e.g., the Netherlands, Belgium, Italy, Finland, Denmark, Sweden, and Greece), and Asia to assess pediatric motor impairments, it has been shown to correlate positively with other pediatric motor assessments used worldwide (Smits-Engelsman et al. 1998; Missiuna et al. 2006) and is well recognized as one of the most extensively utilized motor impairment assessments in the world (Chow and Henderson 2003; Chow et al. 2006a, 2006b; Croce et al. 2001; Tan et al. 2001; Wiat and Darrah 2001).

The MABC norms have been evaluated in studies completed in other cultural contexts including Sweden (Rosblad and Gard 1998), Japan (Miyahara et al. 1998), the Netherlands (Smits-Engelsman et al. 1998), Hong Kong (Chow et al. 2001; Chow et al. 2006), Taiwan (Chow et al.), Israel (Engel-Yeger et al. 2010),

United States (Van Waelvelde et al. 2008), Greece (Ellinoudis et al. 2008), and Singapore (Wright et al. 1994). Generalizability across European cultures has shown to be satisfactory; however, those studies conducted in Hong Kong, Taiwan, Singapore, and Japan suggested some cultural differences existed and that the MABC norms for those countries may need some adjustment (Livesey et al. 2007).

In addition to the worldwide recognition that the MABC has, the instrument has been utilized in many international studies covering a broad range of diagnostic categories such as developmental coordination disorder (DCD), learning disabilities, and autism spectrum disorder (ASD). Additionally, the MABC has been noted to identify more children with motor impairments more successfully (e.g., greater sensitivity and specificity) than that of the “gold standard” *Bruininks-Oseretsky Test of Motor Proficiency* (BOTMP) (Dewey and Wilson 2001), while Crawford et al. (2001) have found that the MABC appears to be more sensitive and is able to better identify children with additional problems associated with learning or attention.

The authors have revised the MABC to generate the MABC-2, a “reliable, easily administered and valid measure of competence in three broad and carefully selected areas of motor performance” (Henderson et al. 2007, p. 117). The three broad motor skill categories that are assessed are (1) Manual Dexterity, (2) Aiming and Catching, and (3) Balance. Changes undertaken to produce the second edition involved revising existing items and introducing some new items. These changes are outlined in two sections below: *test content changes* and *test structure changes* (see Tables 2, 3, and 4 for details).

The MABC-2 *test content changes* are described under three areas: (1) *materials*, (2) *tasks*, and (3) *instructions*:

1. *Materials*: Brightly colored plastic pieces have been introduced to replace pieces originally made of wood. This change was undertaken to standardize the pieces and eliminate any room for variation between kits as well as

Movement Assessment Battery for Children: Second Edition (MABC-2), Table 2 Changes made to age band 1 (3–6 years) from initial version to second edition

Motor skill task	MABC ^a task age band 1	MABC-2 ^b task age band 1
Manual dexterity 1	Post coins	Post coins
Manual dexterity 2	Threading beads	Threading beads
Manual dexterity 3	Bicycle trail	Drawing trail 1 (shape of visual trail has changed)
Aiming and catching 1	Catching beanbag	Catching beanbag
Aiming and catching 2	Rolling ball between goal posts	Throwing beanbag onto mat (new item)

Movement Assessment Battery for Children: Second Edition (MABC-2), Table 3 Changes made to age band 2 (7–10 years) from initial version to second edition

Motor skill task	MABC ^a task age bands 2/3	MABC-2 ^b task age band 2
Manual dexterity 1	Placing pegs/shifting pegs by rows	Placing pegs (new starting position and layout)
Manual dexterity 2	Threading lace/threading nuts on bolt	Threading lace (lacing board is longer)
Manual dexterity 3	Flower visual trail/flower visual trail	Drawing trail 2 (shape of visual trail has changed)
Aiming and catching 1	Two-hand catch/one-hand bounce and catch	Catching with two hands
Aiming and catching 2	Throwing beanbag/throwing beanbag into box	Throwing beanbag onto mat (mat with target now used instead of box)
Balance 1	Stork balance/one-board balance	One-board balance
Balance 2	Heel-to-toe walking/ball balance	Walking heel-to-toe forward
Balance 3	Jumping in squares/hopping in squares	Hopping on mats (mats used for this task)

Henderson et al. 2007, p. 118

^aMABC Movement Assessment Battery for Children

^bMABC-2 Movement Assessment Battery for Children, Second Edition

- taking into account health and safety regulations regarding item pieces when used with children in various settings.
2. **Tasks:** The test has maintained the original structure of the test by retaining eight test items across each age band organized into the three motor skill categories of Manual Dexterity, Aiming and Catching, and Balance. However, individual items have been altered as well as new individual items being introduced. The task changes across the age bands are outlined in Tables 2, 3, and 4.
 3. **Instructions:** In previous research articles, the test instructions of the MABC have been called into question. Although no standardized verbal instructions are included in the second edition, clarification of the administration, scoring of the test, and aspects of tasks to emphasize during demonstration have been provided to minimize the potential for ambiguity. The MABC-2 authors state that this provides flexibility in the mode of presentation and allows the assessor to ensure the examinee understands individual tasks.

^aMABC Movement Assessment Battery for Children
^bMABC-2 Movement Assessment Battery for Children, Second Edition

The MABC-2 *test structure changes* are described under two areas: (1) *age extension* and (2) *reduction of age bands*:

1. *Age Extension*: The MABC-2 has been extended to encompass the assessment of children aged 3 years 0 months–16 years 11 months. The MABC-2 authors believed that a gap existed for the appropriate motor performance assessment for children aged 3 years. In order to assess children of this age, items were slightly adjusted to ensure the attention of a typical 3-year-old could be maintained as well as being fun, easily understood, and requiring minimal verbal communication. Similarly, as the MABC has been utilized and widely recognized for its use with assessment of children with DCD, two sources of requests for suitable motor performance assessments for children aged between 11 and 16 years have been identified. The first is due to the increase in the recognition of DCD as a clinical diagnosis and the importance of early assessment, identification, and intervention service provision to assist with coordination difficulties encountered so as to maximize children’s developmental and motor skills. Current intervention for DCD occurs predominantly in during the primary school years due to the

effectiveness of early intervention. However, the MABC-2 authors have noted that an increasing proportion of adolescents have not been identified earlier with coordination difficulties or have failed to benefit from intervention.

The second source identified was due to ongoing worldwide research into children who have been born “at risk” of damage to their nervous system (e.g., born prematurely). This group of children exhibit cognitive skills within normal limits and do not meet the diagnostic criteria for cerebral palsy, but do experience severe difficulties with their motor performance which in turn affects their academic progression. Therefore, with the development and revision of the MABC, the MABC-2 can provide improved motor performance measurement instrument for younger and older children. This in turn will enable therapists and researchers to develop new intervention techniques, allow for more accurate and sound intervention, and provide a greater understanding of motor performance problems and their consequences over time.

2. *Reduction of Age Bands*: Previously the MABC had 4 ABs; however, pilot work by the test authors provided evidence that existing items could be revised and/or adapted across

the extended age bands. Thus, AB1 and the previous AB4 had an age range of 4 years, and so AB2 and AB3 were collapsed in to one age band. Additionally, and perhaps more importantly, the test authors were aware of problems associated with children changing between age bands in the MABC during the course of an intervention program. Although correlations between similar items across the age bands were high, the authors recognized that they were not perfect. Hence, the final age bands for the MABC-2 are AB1: 3–7 years, AB2: 7–11 years, and AB3: 11–17 years.

The Qualitative Observations section remains a part of the MABC-2 test and allows the testing clinician to supplement the formal test results gathered from administering the Performance Test to a child. A chapter of the manual provides some assistance regarding the process of observation and how to utilize the Qualitative Observations section of the test in conjunction with the formal scores as well as taking into account both motor and non-motor factors that can affect movement and a child's motor performance.

Historical Background

The MABC-2 is a composite of two complementary assessments: the Performance Test and the Checklist. The performance-based portion of the MABC-2 was developed from the *Test of Motor Impairment* (TOMI) (Stott et al. 1972). Development of the TOMI began in 1966 with a primary focus of identifying impaired or nonstandard motor skill performance. Since the TOMI provided little overall motor ability information about the children who were assessed with it, the TOMI was revised in 1984 (see Table 5). This revision, known as the *Test of Motor Impairment-Henderson Revision* (TOMI-H) (Stott et al. 1984), decreased the number of items that a child was required to complete, added a behavioral checklist, and included room for recording qualitative observations related to children's motor skill performance.

Movement Assessment Battery for Children: Second Edition (MABC-2), Table 5 Evolution of the versions of the *Movement Assessment Battery for Children – Second Edition* (MABC-2)

1. *Test of Motor Impairment* (TOMI) (Stott et al. 1972)
 2. *Test of Motor Impairment – Henderson Revision* (TOMI-H) (Stott et al. 1984)
 3. *Movement Assessment Battery for Children* (MABC) (Henderson and Sugden 1992)
 4. *Movement Assessment Battery for Children-2* (MABC-2) (Henderson et al. 2007)
-

In 1992, the Henderson and Sugden *Movement Assessment Battery for Children* (MABC) was published and retained the same items as the TOMI-H (see Table 5). However, the MABC was developed as a means of identifying children aged between 4 and 12 years considered being at risk of a motor impairment, and thus, normative data was added, and the scoring criteria and item descriptions were revised. The MABC consisted of 32 tasks that increased in difficulty across four age bands (AB): 4–6 years, 7–8 years, 9–10 years, and 11–12 years. Simultaneously, Keogh (1968), and subsequently Sugden (1972), developed a teacher checklist which served as preliminary to further evaluative assessments of a child's motor performance and to alert “teachers to the existence of children with movement difficulties” (Henderson et al. 2007, p. 113). Further development has led to it becoming the MABC Checklist (Henderson and Sugden 1992; Reynard 1975; Sugden 1972).

Psychometric Data

Types of reliability data often reported for scales, tests, and measures include internal consistency, test-retest/time sampling reliability/temporal stability, inter-rater/inter-scorer reliability, intra-rater/intra-scorer reliability, alternate form reliability, and split-half reliability (American Educational Research Association [AERA], American Psychological Association [APA], & National Council on Measurement in Education [NCME] 1999; Anastasi and Urbina 1997). Types

of validity often reported for tests include face validity, content validity, criterion-related validity, and construct validity (AERA et al. 1999). Two subtypes of criterion-related validity frequently included are concurrent validity and predictive validity, while subtypes of construct validity often reported include factor analysis validity, discriminant validity, convergent validity, divergent validity, diagnostic validity, and rating scale validity (Fawcett 2007). Details of the reliability and validity of the MABC-2 are reported in its manual.

The MABC-2 is a major revision of the well-known and frequently used MABC (Barnett and Henderson 1998; Henderson et al. 2007). The test authors assume that the reliability data and validity information reported for the MABC are generalizable to the MABC-2. “Confidence in the MABC-2 score interpretation can be derived not only from the UK standardisation study but also from the extensive validation data reported in this and earlier manuals” (Henderson et al. 2007, p. 132). The MABC and MABC-2 may assess the same motor skill constructs in a similar format, but since the MABC-2 has added four new items, revised some of the retained items, reduced number of age ABs (the MABC had 4 ABs, while the MABC-2 has 3), and increased age range that it covers (the MABC-2 now covers ages 3–17 years), it is essentially a new, discrete test that needs to have its own specific measurement properties evaluated singly. This appears to be an inaccurate assumption made by the MABC-2 authors.

The MABC-2 test manual reports some preliminary reliability data for its Performance Test based on the results of several studies completed by other investigators that involved experimental versions of the MABC-2 AB1 and AB3 tasks (see Table 6). Visser and Jongmans (2004) investigated the test-retest results for the MABC-2 AB1 with a group of 55 3-year-old children from the Netherlands. Chow et al. (2002), in another study involving a sample of 31 adolescents, evaluated the inter-rater and test-retest reliability of a translated version of the MABC-2 AB3 tasks into Chinese. Smits-Engelsman et al. (2008) reported about the inter-rater reliability of the MABC-2. In

another inquiry involving 64 young adults, Faber and Nijhuis van der Sanden (2004) examined the intra-rater and inter-rater reliability of a total score calculated for the MABC-2 AB3 tasks originally used by Chow et al. (2002). Details of the translation process for the Chinese version of the MABC-2 AB3 tasks used in the Chow et al. (2002) study were not reported in the test manual. Similarly, it was not reported if the version of the MABC-2 AB1 tasks used in the Visser and Jongmans (2004) investigation was translated into another language since it was used in the Netherlands. The studies completed by Visser and Jongmans (2004) and Faber and Nijhuis van der Sanden (2004) are both unpublished manuscripts, thus have not been peer reviewed nor are they readily accessible for review. The Faber and Nijhuis van der Sanden (2004) study involved 64 young adults aged between 18 and 28 which were outside the age limits of the MABC-2 and the geographical location where the study was completed was not reported. With all of these studies, there are issues of cultural context, translation of the MABC-2 Performance Test items, and only evaluating one AB at a time.

Henderson et al. (2007) reported a test-retest study involving 20 3-year-old children. Pearson product moment correlations ranged from 0.86 to 0.91 for the three Manual Dexterity tasks, while the Aiming and Catching and Balance tasks were less reliable with coefficients of 0.48 and 0.68. The test authors suggested that the test-retest reliability problems lie with younger children, aged between 3 and 4 years. In another study completed by the test authors, the test-retest reliability of the whole test involving all three ABs was completed. Sixty children, 20 from each AB, were included. Using the standard scores for the three test sections (Manual Dexterity, Aiming and Catching, and Balance) as well as the total test score, the Pearson product moment correlations were 0.77, 0.84, 0.73, and 0.80, respectively (Henderson et al. 2007). This indicates reasonable test-retest reliability results for the MABC-2. It would have been informative if the test authors had completed similar studies evaluating the intra-rater reliability, inter-rater reliability, and internal consistency of the Manual Dexterity, Aiming and Catching,

Movement Assessment Battery for Children: Second Edition (MABC-2), Table 6 *Movement Assessment Battery for Children – Second Edition (MABC-2; Henderson*

et al. 2007) summary of MABC-2 Performance Test and Checklist validity and reliability data

Test section	MABC-2 performance test	MABC-2 checklist
Reliability data reported	Limited reliability data reported is reported in the manual that is specific to the MABC-2. A study completed by Visser and Jongmans (2004) that reports test-retest results for AB1 for a group of 55 3-year-old children from the Netherlands is included in the test manual. Pearson product moment correlations ranged from 0.49 to 0.70 The test authors reported a second test-retest study involving 20 3-year-old children. Pearson product moment correlations ranged from 0.86 to 0.91 for the three manual dexterity tasks, while the aiming and catching tasks were less reliable with coefficients of 0.48 and 0.68. The test authors suggest that the test-retest reliability problems lie with younger children, aged between 3 and 4 years In another study that involved a translated version of AB3 tasks into Chinese, inter-rater reliability and test-retest reliability were evaluated on a sample of 31 teenagers by Chow et al. (2002). Intraclass correlation (ICC) coefficients for inter-rater reliability ranged from 0.92 to 1.00, while test-retest coefficients ranged from 0.62 to 0.92 In another study involving 64 young adults, Faber and Nijhuis van der Sanden (2004) examined the intra-rater and inter-rater reliability of a total score calculated for the AB3 tasks originally used by Chow et al. (2002). The ICC scores were 0.79 (intra-rater) and 0.79 (inter-rater) In a final study completed on the test authors, the test-retest reliability of the whole test involving all three ABs was completed. Sixty children, 20 from each AB, were included. Using the standard scores for the three test sections (manual dexterity, aiming and catching, and balance) as well as the total test score, the Pearson product moment correlations were 0.77, 0.84, 0.73, and 0.80, respectively	The test manual states that no reliability data has been collected on the MABC-2 checklist; thus, none is reported. The test authors do report reliability data about the MABC checklist, but this is redundant since the MABC-2 checklist has been revised
Validity data reported	Extensive validity data about the MABC is reported in the manual, and limited preliminary validity evidence (content, face, criterion-related) about the MABC-2 is also reported. Content validity of the MABC-2 was established by input of an expert panel. According the test manual, the expert panel was unanimous that the MABC-2 contents/items were representative of the motor domain it was intended to evaluate The test manual reports that face validity has been established by feedback obtained from a wide range of professionals who have used the MABC including psychologists, therapists, educational	Two validity studies are reported in the test manual. The first study involves a group of 20 children with DCD ages 6–11 years (Barnett et al. 2007). The MABC checklist was completed by the children’s parents. Scatterplots of section A and section B of the checklist suggested a weak relationship between the two section scores. The MABC-2 checklist traffic light system was able to indicate that the children continued to have motor skill difficulties in 19 of the 20 children. The test authors claim that this is evidence of criterion-related validity, but this is not clearly demonstrated

(continued)

Movement Assessment Battery for Children: Second Edition (MABC-2), Table 6 (continued)

Test section	MABC-2 performance test	MABC-2 checklist
	professionals, and physicians. The face validity appears to be based on the MABC and not the MABC-2 The test manual reports subtest and total test standard score correlations as evidence of the MABC-2 subtests evaluating related, but different motor abilities. The manual dexterity subtest was correlated with the aiming and catching (0.26), balance (0.36), and total test score (0.76). The aiming and catching subtest was correlated with the balance (0.25) and the total test score (0.65). The balance subtest was correlated with the total test score (0.73) Evidence of criterion-related validity of the MABC-2 was reported in three studies in the test manual. First, using a sample of 31 Cypriot children, Kavazi (2006) examined the relationship MABC-2 manual dexterity items and the children’s performance on the Goodenough and Harris draw-a-man test. Correlations with the posting coins and drawing trail items and the draw-a-man test were 0.66 The preliminary results of a second study completed by the test authors involving a small sample of 20 children who were initially assessed with the MABC and were reassessed using the MABC-2. The MABC-2 was able to indicate that the children continued to have motor skill difficulties. The type of validity being evaluated here is not clearly reported. The third study reports the results of 25 boys diagnosed with Asperger’s syndrome who were assessed by the MABC-2 (Siaperas et al. 2007). The MABC-2 total test scores indicated that the majority of the boys (21/25) have impaired motor skills. The test authors are purporting that this is evidence of the MABC’s discriminative validity	The second study involves 24 boys with Asperger’s syndrome with a mean age of 13.3 years (Siaperas et al. 2007). The MABC checklist was completed by the children’s parents. The MABC-2 checklist traffic light system was able to indicate that in 23 of the 24 boys with Asperger’s syndrome experienced motor skill difficulties. Again, the test authors make the claim that this is evidence of criterion-related validity, but how this is actually demonstrated is not clear
Clinical utility	The MABC-2 appears to have reasonable to good clinical utility. The international recognition of the MABC and its use with identifying children with DCD as well as other motor impairments has seen it become one of the most commonly utilized motor assessments. In addition, the brevity of the test across a wide age range of children furthermore enhances the utility of the MABC-2 in various clinical, educational, and research contexts. In summary, the MABC-2 is an improvement over the MABC and is best used as a screening instrument. Blank et al. (2012) noted that attentional problems in children may impact on their performance on the MABC-2 and that “there seems to be a training effect of the M-ABC if repeated within 4 weeks, although this effect seems to be less in children with severe DCD” (p. 71)	

and Balance test sections as well as the total test score involving all three MABC-2 ABs. At this time, this fundamental information is lacking.

The test manual states that no reliability data has been collected on the MABC-2 Checklist; thus, none is reported. The test authors do report reliability data about the MABC Checklist, but this is redundant since the MABC-2 Checklist has been revised. Test-retest reliability and internal consistency reliability data needs to be reported about the MABC-2 Checklist.

When it comes to the validity of the MABC, the test authors include a large body of evidence in the MABC-2 test manual (Barnett and Henderson 1998; Henderson et al. 2007). However, generalizations from the MABC's validity findings to the MABC-2's validity cannot be readily made for a number of reasons. First, the age range is different between the two test versions with the MABC-2 now including children as young as 3 years and adolescents as old as 16 years. The ABs have fundamentally changed between the two test versions. The MABC ABs 2 and 3 have been collapsed into the MABC-2 AB 2. Finally, a number of test items have been revised, and four new test items have been added to the MABC-2. Hence, the validity properties of the first test cannot be generalized to the newer revised version in the opinion of this author.

Limited preliminary content, face, criterion-related validity, and evidence about the MABC-2 Performance Test are reported in its test manual. Content validity of the MABC-2 Performance Test was established by input of an expert panel. According to the test manual, the expert panel was unanimous that the Performance Test contents/items were representative of the motor domain it was intended to evaluate. The content validity of the MABC-2 Performance Test appears reasonable (see Table 6). The test manual reports that face validity has been established by feedback obtained from a wide range of professionals who have used the MABC including psychologists, therapists, educational professionals, and physicians. However, the face validity appears to be based on the MABC and not the MABC-2 Performance Test. Similarly, face validity of an instrument does not have inherent psychometric,

objective, or numeric data attached to it to ensure that an instrument is evaluating the skills, attributes, or constructs it claims to assess. Face validity is mainly based on an overall subjective impression of a test (AERA et al. 1999).

The test manual reported section and total test standard score correlations as evidence of the three MABC-2 Performance Test sections evaluating related but distinct motor skill abilities (see Table 6). The Manual Dexterity section was correlated with the Aiming and Catching section (0.26), Balance section (0.36), and MABC-2 total test score (0.76). The Aiming and Catching section was correlated with the Balance section (0.25) and the total test score (0.65). The Balance section was correlated with the total test score (0.73). This provides evidence that the three MABC-2 Performance Test sections are measuring related but discrete skills and "the fact that each component correlates well with the Total Test Score is re-assuring" (Henderson et al. 2007, p. 142).

Evidence of criterion-related validity of the MABC-2 Performance Test was reported in the form of three studies in the test manual (see Table 6). First, enlisting a sample of 31 Cypriot children, Kavazi (2006) examined the relationship MABC-2 Manual Dexterity section items and the children's performance on the *Goodenough and Harris Draw-a-Man Test* (Goodenough and Harris 1963). Correlations with the Posting Coins and Drawing Trail items and the Draw-a-Man Test were 0.66. Limitations of this study were a small sample size (31 children) and correlating the children's fine motor skill performance with their performance on an outdated person drawing test. Given the fact that the Kavazi study only involved the Manual Dexterity section items from one MABC-2 AB1, the concurrent validity results are not generalizable to the whole measure. The scope of the Kavazi (2006) study was very narrow.

The preliminary results of a second study completed by the test authors involved a small sample of 20 children who were initially assessed with the MABC and were reassessed using the MABC-2 Performance Test (Henderson et al. 2007). The MABC-2 was able to indicate that the children

continued to have ongoing motor skill difficulties. The type of validity being evaluated here was not evident to the reader. It would have been more prudent to compare the whole MABC-2 to a well-established motor skill tests such as the *Peabody Developmental Motor Scales – 2nd edition* (PDMS-2) or the *Bruininks-Oseretsky Test of Motor Proficiency, 2nd edition* (BOT-2). Spironello et al. (2010) examined the construct validity and concurrent validity between the short form of the BOTMP and the MABC, while Van Waelvelde et al. (2007a) investigated the convergent validity between the MABC and the PDMS-2.

The third study reported the results of 25 boys diagnosed with Asperger's syndrome who were assessed by the MABC-2 Performance Test Siaperas et al. (2007). The MABC-2 Performance Test total scores indicated that the majority of the boys (21/25) had impaired motor skills. The test authors purported that this is evidence of the MABC-2 Performance Test's discriminative validity. The study by Siaperas et al. (2007) did not include a matched control group for comparison purposes, therefore, claims that the MABC-2 exhibits discriminant validity cannot really be supported.

One major weakness with the validity evidence reported in the MABC-2 test manual is the lack of construct validity evidence. There is no evidence that clearly indicated the MABC-2 Performance Test items are actually evaluating the motor skill constructs they claim they are. Evidence of construct validity can include divergent/convergent validity, factor analysis validity, diagnostic validity, rating scale validity, and/or discriminative validity. The completion of a confirmatory factor analysis, a component of classical test theory, would provide valuable evidence if the items from the Manual Dexterity, Aiming and Catching, and Balance sections load on three discrete factors and whether the eight items that make the whole MABC-2 load on one overall motor impairment factor. Hypotheses about the MABC-2 Performance Test factor structure need to be explored further (Anastasi and Urbina 1997). Blank et al. (2012) noted that there "is a lack of research on the discriminant validity of the M-ABC" (p. 71).

In regard to the MABC-2 Checklist, two validity studies are reported in the test manual (see Table 6). The first study involves a group of 20 children with DCD ages 6–11 years (Barnett et al. 2007). The MABC Checklist was completed by the children's parents. Scatterplots of Section A and Section B of the Checklist suggested a weak relationship between the two section scores. The MABC-2 Checklist Traffic Light system was able to indicate that 19 of the 20 children continued to have motor skill difficulties. The test authors claim that this is evidence of criterion-related validity, but how this is demonstrated is not clear.

The second MABC-2 Checklist study involved 24 boys with Asperger's syndrome with a mean age of 13.3 years (Siaperas et al. 2007). The MABC-2 Checklist was completed by the children's parents. The MABC-2 Checklist Traffic Light system was able to indicate that 23 of the 24 boys with Asperger's syndrome experienced motor skill difficulties. Again, the test authors make the claim that this is evidence of criterion-related validity, but how this is actually demonstrated is not clear. Similar to the MABC-2 Performance Test, the Checklist has limited content, concurrent, and construct validity evidence. Further validity evidence is needed since one is left asking the question: do the MABC-2 Checklist items load on the constructs they claim to measure?

A number of studies have been completed by other researchers that have evaluated different aspects of the MABC-2's reliability. These studies have been completed in a variety of cross-cultural settings as well including Greece, Norway, Japan, mainland China, Taiwan, Israel, and Australia. This provides valuable insights about how suitable the MABC-2 is for use in cross-cultural settings. For example, Engel-Yeger et al. (2010) examined the construct validity of the MABC-2 and its appropriateness to use in Israel. Participants in the study were 249 typically developing children between four and 12 years of age. The findings indicated that children's age and gender, as well as mother's education level and socioeconomic status had an influence on the children's motor performance as assessed by the MABC-2.

Engel-Yeger et al. (2010) concluded that the “M-ABC may serve as a suitable tool for examining the motor performance of children in Israel” (p. 87).

In a Greek setting, Ellinoudis et al. (2011) completed an investigation of the reliability and validity of the age band 1 of the MABC-2 involving 183 children ranging in from 36 to 64 months old (mean = 50 months, SD = 9 months). “Cronbach’s alpha coefficient values were 0.51, 0.70 and 0.66 for manual dexterity, aiming and catching, and balance task groups, respectively” (Ellinoudis et al. 2011, p. 1049). Thirty children completed the age band 1 of the MABC-2 items on two occasions 1 week apart. The test-retest reliability correlations for the eight items ranged from 0.66 to 0.96 and for the manual dexterity, aiming and catching, balance task and total scores were 0.82, 0.61, 0.90, and 0.85. “A confirmatory factor analysis was performed to test the goodness-of-fit of the items. The analysis revealed values for the three-domain model (manual dexterity, aiming and catching and balance) that are similar to the structure proposed by Henderson et al. (2007)” (Ellinoudis et al. 2011, p. 1049).

Wuang et al. (2012a) examined the internal consistency, test-retest reliability, and responsiveness to change of the MABC-2 in a group of 144 children from Taiwan diagnosed with DCD. A Cronbach alpha of 0.90 was reported for the internal consistency coefficient for the MABC-2 while the coefficients for the Manual Dexterity, Aiming and Catching, and Balance subscales were 0.81, 0.84, and 0.88, respectively. An intraclass correlation coefficient of 0.97 was reported as the test-retest reliability for the MABC-2 total score for a 20-day interval between test administrations and the ICCs for the items ranging between 0.88 and 0.88. “The minimal detectable change was 0.28 points whereas the minimal important difference (MID) values were from 2.36 to 2.50” (Wuang et al. 2012, p. 160). The authors suggest that the minimal detectable change and minimal important difference scores for the MABC-2 provide the point of reference for practitioner decision-making in clinical management of children presenting with DCD.

Similar to the study by Ellinoudis et al. (2011), Hua et al. (2013) evaluated the internal consistency, test-retest reliability, criterion-related validity, and construct validity of the age band 1 of MABC-2. Children from mainland China were recruited from 10 public nursery schools with resultant sample size of 1823 participants (915 boys and 908 girls) aged 36–72 months old (mean = 61.284 months, SD = 10.212 months). The Cronbach’s alpha coefficient for the eight age band 1 MABC-2 items ranged from 0.43 to 0.52 (Hua et al. 2013). The test-retest reliability ($n = 184$) ranged between 0.83 and 0.99 for the eight age band 1 MABC-2 items with a 14-day interval between test administrations (Hua et al. 2013). The inter-rater reliability ($n = 184$) for the eight age band 1 MABC-2 items ranged between 0.89 and 0.99 (Hua et al. 2013). A subsample of 184 children completed both the MABC-2 and the PDMS-2 and their scores were correlated. The correlations between the PDMS-2 total scale scores and the MABC-2 Manual Dexterity, Aiming and Catching, and Balance subscales and Total scores were 0.38, 0.063, 0.17, and 0.63, respectively (Hua et al. 2013). “The results showed that the total standard scores on the two tests were correlated moderately with each other” (Hua et al. 2013, p. 805). The authors completed a confirmatory factor analysis to examine the three-factor structure of the MABC-2 with the eight items as proposed by Henderson et al. (2007). The CFA results indicated that a six-item version of the MABC-2 met the goodness-of-fit indices of the adjusted model (each above 0.9), indicating a reasonable fit to the model. “The factor loadings of two items (‘Drawing trail’ and ‘Walking heels raised’) for their domains in the model were not significant statistically” (Hua et al. 2013, p. 807).

Kita et al. (2016) investigated the applicability of the MABC-2 age band 2 to Japanese children. A group of 132 typically developing Japanese children completed the age band 2 assessment items. The internal consistency, factorial validity, gender differences, and a comparison to the MABC-2 normative sample was examined. Cronbach’s alpha coefficient for the eight test items was 0.602 and ranged from 0.53 to 0.58.

All indices from the confirmatory factor analysis of the eight MABC-2 items indicated “a good fit between the postulated model and the data” and “these results demonstrated high factorial validity of the AB2 in the Japanese samples” (Kita et al. 2016, p. 710). When the item scores were in the Japanese sample were compared with the MABC-2 normative sample, the results suggested that the sample of Japanese children overall tended to have higher scores on the age band 2 compared with the group of MABC-2 normative sample who were British children (Kita et al. 2016). When the performance of Japanese boys and girls were compared on the three MABC-2 domain scores, girls obtained higher scores on Manual Dexterity and Balance while there were no significant gender differences in Aiming and Catching.

Thirty-eight children and parents was recruited from Victoria, Australia were recruited by Kennedy et al. (2013) to investigate whether the Physical Self-Description Questionnaire completed by children or the MABC-2 Checklist completed by the parents of the children were predictive of the children’s BOT-2 performance results. The findings indicated that two significant predictive relationships were identified based on parents’ report of their children’s motor skills: (i) the total score of the MABC-2 Checklist was found to be a significant predictor of the BOT-2 Manual Coordination motor composite score, accounting for 8.35% of its variance, and (ii) the MABC-2 Checklist total score was a significant predictor of the BOT-2 Strength and Agility motor composite score, accounting for 11.6% of its variance (Kennedy et al. 2013). No predictive relationships were identified between the PSDQ and the BOT-2 performance scores.

Holm et al. (2013) investigated the intra- and inter-rater reliability of the MABC-2 amongst a group of 45 healthy children from Norway (mean age 8.7 years). Thirty children were included in the inter-rater reliability component of the study, 29 children in the intra-rater part, 14 of them took part in both studies. Qualified physiotherapists completed the MABC-2 assessments. The intra-rater reliability test administrations occurred 1–2 weeks apart. The ICC values for the intra-

rater reliability of eight MABC-2 items ranged from 0.24 to 0.77 (Holm et al. 2013). For the three age band 2 domains, the intra-rater reliability ICCs were 0.62 for manual dexterity, 0.49 for aiming and catching, and 0.49 for balance (Holm et al. 2013). For the MABC-2 total test score, the intra-rater reliability ICC was 0.68. In relation to inter-rater reliability, for the MABC-2 age band 2 items, the ICCs ranged from 0.39 to 0.68. For the three age band 2 domains, the inter-rater reliability ICCs were 0.63 for manual dexterity, 0.77 for aiming and catching, and 0.29 for balance (Holm et al. 2013). The inter-rater reliability for the MABC-2 age band 2 total test score was 0.62. The authors concluded that while the MABC-2 exhibited reasonable intra- and inter-rater reliability, the “findings may indicate that the MABC-2 might be more suitable for diagnostic or clinical decision making purposes, than for evaluation of change over time” (Holm et al. 2013, p. 799).

Lane and Brown (2015) investigated the convergent validity between BOT-2 and the MABC-2 age bands 2 and 3. A sample of 50 children from Australia with no history of motor or intellectual problems was recruited. The results of the study indicated that MABC-2 age band 3 was significantly associated with the BOT-2; however, there were no significant correlations between the MABC-2 age band 2 and the BOT-2.

Clinical Uses

The MABC, and now the MABC-2, is one of the most widely used pediatric motor impairment assessments (Getchell et al. 2007; Livesey et al. 2007; Slater et al. 2010; Van Waelvelde et al. 2007b). It has been used to assess a variety of diagnostic groups including children with (1) attention deficit/hyperactivity disorder (ADHD) (Miyahara et al. 2006; Pitcher et al. 2003), (2) autistic spectrum disorders (ASD) (Green et al. 2002; Liu and Breslin 2013; Smith 2004), (3) special language impairments (Hill et al. 1998), (4) developmental coordination disorder (DCD) (Cairney et al. 2009; Chen et al. 2009; Chow et al. 2006; Cox et al. 2015; Niemeijer et al. 2006; Rosblad and Gard 1998;

Ruckser-Scherb et al. 2013; Spittle et al. 2013), (5) cognitive impairments or learning difficulties (Henderson and Sugden 1992; Jongmans et al. 2003), and (6) hearing impairment (De Kegel et al. 2012). Other diagnostic studies where the MABC has been used include congenital hypothyroidism (Kooistra et al. 1998), childhood encephalitis (Rantala et al. 1991), epilepsy (Beckung et al. 1994), neurofibromatosis 1 (North et al. 1994), generalized joint hypermobility (de Boer et al. 2015), birth-related brachial plexus injury (Bellows et al. 2015), hemiplegia (Mercuri et al. 1999), preterm infants at older ages who are at risk for poor motor outcomes (Brown et al. 2015; Keunen et al. 2016; Setänen et al. 2016), and intellectual disability (Wuang et al. 2012). Individuals diagnosed with ASD, Asperger's syndrome (AS), and other related pervasive developmental disorders (PDD) often present with motor skill difficulties (Dziuk et al. 2007; Fournier et al. 2010; Fuentes et al. 2009; Gidley Larson and Mostofsky 2006; Green et al. 2009; Jasmin et al. 2009; Ozonoff et al. 2008; Pan et al. 2009; Provost et al. 2007; Staples and Reid 2010). Hence, the MABC-2 is a useful and relevant measure to use when assessing children with ASD, AS, PDD, and other related diagnoses.

The MABC-2 Performance Test and Checklist items provide invaluable information for practitioners related to the identification of and intervention with children presenting with motor difficulties. It can be used in a range of settings including clinical, community-based, child care, early intervention, early childhood education, primary and secondary school settings, private practice, hospital, and rehabilitation. It can be used as either a quick screening instrument or as one component of a comprehensive diagnostic evaluation. The MABC-2 Performance Test and Checklist items can be used by a variety of health and education professionals (including occupational therapists, psychologists, early childhood education teachers, social workers, counselors, physiotherapists, speech-language pathologists, nurses, pediatricians, physicians, and early intervention specialists among others) to evaluate the motor skills of children and adolescents aged 3–17 years.

It is recommended that other sources of information (e.g., medical records, clinical observations, interviews with parents and teachers) be accessed as well. The clinical purposes the MABC-2 could be used for are establishing the baseline of a client's gross and fine motor skills (often done in the context of an initial assessment), assisting with the formulation of a client's intervention goals, monitoring a client's progress after receiving intervention/remedial services, or providing evidence to justify the need for a client to receive continued services. The MABC-2 Performance Test and Checklist can also be used for research purposes such as evaluating the effectiveness of educational, psychological, therapeutic, or medical services provided to pediatric clients. Two limitations were recently noted about the MABC-2 by Blank et al. (2012): (i) the potential for floor effects in task age band 1 for children 3–6 years of age and (ii) the “discontinuation’ of the scales moving from one age band to another may be a problem in longitudinal comparisons, when children, for example, move from kindergarten to school age and for the comparison of children in first grade (6- to 7-year-olds)” (p. 71) since these age bands are often significant for the diagnosis and treatment monitoring of DCD.

In a recent review of assessment tools that are recommended for use with children presenting with suspected DCD at the 2011 European Academy for Childhood Disability, Blank et al. (2012) stated that the studies published about the MABC-2 “show good to excellent interrater reliability, good to excellent test–retest reliability and fair to good validity (construct validity and concurrent validity with BOTMP)” (p. 71). Blank et al. (2012) also remarked that considering the overall “strengths and limitations of the M-ABC, the level of evidence on quality and suitability of the M-ABC (-2) for the diagnosis of DCD (SDDMF) is rated as moderate to good” (p. 71). In summary, the MABC-2 is highly recommended for use by practitioners. It can play an important role in the assessment of and intervention planning for children and adolescents presenting with ASD, AS, and PDD.

Definition

This chapter focuses on the topic of character portrayals with autism spectrum disorders (ASD) in film and TV-series. We address this topic by presenting research from the general psychiatric field before we discuss the research on portrayals of characters with ASD. We will also provide the reader with some examples of films and TV-series that have been given particular attention in the popular media and that will be known to many, also outside of the autism community. We address both advantages and disadvantages that are consequences of popular-media portrayals of ASD.

Historical Background

In the last few years, there has been a surge of new characters in fictional film and in TV-shows that either are labelled as having an autism spectrum disorder by the makers or by the public due to resembling traits and behaviors of the characters with that on the autism spectrum. In general, portrayals of people with psychiatric disorders in film and TV-series are not an uncommon topic of research particularly in disciplines like psychiatry and media-science (Butler and Hyler 2005; Stuart 2006) but may also be found in fields like sociology in, for instance, analyzing trends in society. Conditions like memory loss or disorders like schizophrenia, depression, anxiety, and split personality have been thoroughly addressed (REF). Schneider notes that the link between psychiatry and movies go as far back as to the start of the twentieth century with films like “*The Escapees from Charenton*” in 1901 (released in Britain under the name “*Off to Bedlam*,” and in USA under the name “*Off to Bloomingdale Asylum*”) (Schneider 1987). Whether it is portrayals of psychiatrists or persons with psychiatric disorders, there are a lot of films, from drama to thrillers, from horror to comedy, available. Some of the films may be regarded as classics and films like “*The Three Faces of Eve*” (1957), “*Psycho*” (1960), “*One Flew Over the Cuckoo’s Nest*” (1975), “*Fight Club*” (1999), or “*Shutter Island*” (2010) and have had an impact on public perceptions of psychiatric disorders. Such portrayal on the screen influences the individual patient and their family, healthcare professionals, and policymakers as well as contributing to affect global, societal attitudes (Wahl 1995). However, a problem is that representations of psychiatric disorders in the mass media are often inaccurate and often overrepresent links between, for instance, violence and mental illness (Edney 2004; Stout et al. 2004; Thornton and Wahl 1996; Wahl 2003). Also, fictional portrayals of persons with psychiatric disorders or neurological conditions on film have also contributed to mystification and misconceptions. For instance, portrayals of amnesia on film and TV usually bear little resemblance to reality and in turn distort

public conception of the condition (Baxendale 2004; Hacking 2009). Further, Butler and Hyler (2005) argue that it is a common feat in Hollywood movie portrayals of children and adolescents with mental health issues or psychiatric disorder to be presented in a mythical fashion, which may be harmful in terms of misguiding public understanding of different conditions and disorders.

During the past couple of decades, portraying characters with autism spectrum disorders (ASD) have become very popular in films and in TV-shows. So much that autism is now, by many, regarded as part of the general pop-culture (Belcher and Maich 2014; Hacking 2009). Since TV and film are highly influential sources in shaping public perception of ASD, surpassing sources like clinicians, researchers, or actual encounters with people on the spectrum, it is important to address and investigate in what ways characters in TV and film are portrayed.

Current Knowledge

ASD, once considered a rare disorder, is today regarded as a common neurodevelopmental disorder or condition with estimates of prevalence somewhere around 1% in the population (Baird et al. 2006; Kogan et al. 2009).

Following the breakthrough film *Rain Man* (1988), the increase in characters with ASD in films and TV-series has been substantial (Conn and Bhugra 2012; Hacking 2010). Of course, there are examples of characters that have been portrayed as having autistic traits and behaviors before the 1980s, for example, “Philip” in “*Run Wild, Run Free*” from 1969, and “Chance, the gardener” in “*Being There*” from 1979, but the knowledge of autism at that point in time was limited and the disorder was not even a formal diagnosis in DSM before 1980. Either way it is safe to say that the release of the movie *Rain Man* marks a starting point for when autism, both as a term and as a disorder, reached a larger part of the society’s perception.

As discussed by Damjanovic et al. (2009) and Draaisma (2009), characters with ASD on film

and TV may contributed in influencing public knowledge and shaping attitudes towards the condition. But how are characters with ASD portrayed on the screen? As we noted, earlier films with characters with psychiatric disorders are known to presenting disorders in an unfortunate way in terms of, for instance, violent behaviors. However, autistic characters are typically not portrayed in this way. Instead, some argue that characters with ASD have a tendency to be portrayed more like heroes (Belcher and Maich 2014) and with special talents (Hacking 2009) and although this perhaps looks fine at first glance it may not give an accurate picture of ASD.

Publications in scholarly journals on the topic of ASD on TV can be found in various disciplines such as film history, media, philosophy, sociology, psychology, and psychiatry to name a few. Many of the publications take the form of in-depth analyses on advantages and disadvantages of portrayals of ASD on screen. Examples of key publications here are Douwe Draaisma's article on Stereotypes of autism (2009) and Stuart Murray's article where the public consciousness of autism is analyzed in light of the increased fascination of the disorder (2006). Other publications are case studies where a character in a film or TV-show is being dissected in light of his or her ASD-diagnosis or his or her autistic like traits or behaviors (see for instance Cockain 2016; Tobia and Thoma 2015).

There are few studies that report on quantitative data from larger samples of films portraying characters with ASD. Conn and Bhugra (2012) described a sample of 23 films noting that most films with characters with ASD are in the drama genre. They also argue that although there are concerns as to whether portrayals are realistic or not, there are possibilities for using fictional films for educational purposes within health sciences such as medicine and psychiatry.

Another quantitative approach on autism and film was undertaken in a PhD thesis published in 2014 (Garner 2014) as well as a publication the following year (Garner et al. 2015). Garner and colleagues used the Childhood Autism Rating Scale – Second edition (CARS2: Schopler et al. 2010) to score 15 characters with ASD from

various films. The authors concluded that character portrayals, compared to an average autism-affected population, were more severe in their display of autism symptomology (Garner et al. 2015).

A recent study used the DSM-5 (APA 2013) to investigate whether diagnostic criteria lined up with behaviors and traits displayed by fictional portrayals of characters with ASD (Nordahl-Hansen et al. 2017). In the sample of 26, there were 22 films and 4 TV-series that included characters in highly popular TV-series that has been linked to the autism spectrum (*Community*, 2009–2015, *The Big Bang Theory*, 2007–, *The Bridge*, 2011–, *Alphas*, 2011–2012). The results from this study was much in line with results found in Garner et al. (2015) as a majority in the sample was in very close alignment with DSM-5 diagnostic criteria for an autism spectrum diagnosis.

In general, the researchers conclude that character portrayals are somehow overemphasized when it comes to displaying autistic traits, which in turn may reinforce stereotypes of the disorder. This is interesting in considering a common criticism from the autism community that most portrayals, at least this past decade, are so-called “high-functioning” verbal characters with low levels of support needed in, for instance, everyday living. In this respect, it is interesting to note that a character like Abed Nadir in the TV-show “*Community*” has the lowest score on autistic traits in the Nordahl-Hansen et al. (2017) sample but is one of the most embraced characters in various “Asperger-communities.”

A topic of very high interest to the people making films and TV-shows about fictional characters with ASD that display exceptional skills or savant skills. It is easy to understand that savant skills are fascinating and just as easy to understand that screenwriters “give” these features to their characters in the hopes of making them more interesting. However, this has led to the impression that savant skills are something that most people with ASD have. But, for instance, the DSM-5 criteria for ASD (APA 2013) do not make particular notice of savant skills or savant syndrome although fixated or special interests

may or may not be regarded as savant like skills. It is not clear how many individuals within the ASD population that actually have savant skills much due to varying definitions of what constitutes savant skills. However, research indicates that the prevalence might be somewhere between 10% (Treffert 2014) to approximately 30% (Howlin et al. 2009) within the ASD population. Although these prevalence estimates are higher than in other populations, it is not a common feat in persons with ASD. Even so, there is a tendency to portray characters with ASD on screen as having savant skills (Conn and Bhugra 2012; Garner et al. 2015; Nordahl-Hansen et al. 2017) or as being intellectually stimulating geniuses (Belcher and Maich 2014).

Future Directions

Although there are similarities between many films and TV-shows in the ways characters with ASD are portrayed, there are also large differences both in terms of the portrayals but also of thematic difficulties addressed. Some films show scenes that will relate to families and people on the spectrum. Problems as a consequence of hypersensitivity to environmental stimuli, problems in school and struggles with academic success to severe bullying are some recurring themes. Further, difficulties regarding dating, sex, and relationships are frequent topic but also more overarching existential issues and general difficulties with social communication that leads to feelings of social ostracism. Nevertheless, critique has been raised about the overrepresentation of middle-class white males either in their teens or young adults that are so-called “high functioning.” This is particularly evident in the typical “Hollywood” mainstream portrayals of ASD and the debate has increased in strength following the release of TV-series like “*The Big Bang Theory*” and more recently “*The Good Doctor*” and “*Atypical*,” the latter two both aired for the first time in autumn 2017.

For the purposes of giving the public a nuanced view of the heterogeneity that resides within the autistic spectrum, a variety of portrayals of

persons with ASD on screen would be a step in the right direction. That being said, one character portrayal in a film or TV-show cannot capture the complexity that resides with the entire autism spectrum, nor do justice to the variety of autistic lived experience (Nordahl-Hansen 2017). There are, however, fictional films and TV-series available that portray characters with ASD in a wide variety of ways but many of these depictions do not reach as wide an audience as the so-called mainstream “Hollywood” productions. In addition to more films and TV-series portraying characters with ASD that have higher needs of everyday support, it would be welcoming to see more films with characters that are minimally or nonverbal or even display self-injurious behaviors. Further, although there are exceptions, like *Snow Cake* (2006), *The Bridge* (2011–), *Fly Away* (2011), *Molly* (1999), and *Mozart and the Whale* (2005) to name a few, more female characters with ASD on film and TV would also be welcome.

Additionally, portrayals of autism and aging is almost entirely missing; so although there has been a marked increase in characters with ASD in fictional films and TV-shows, there are still many gaps to fill.

Many of the films and TV-series that are available can be viewed by children but in most cases, parental guidance are encouraged but British and American TV-channels have started including characters with ASD in TV-programs that target the child as the main consumer. It is of high importance that character portrayals of persons with ASD on TV for kids do not lead to stereotype thinking of the disorder. If portrayed with care, respect, and adjusted to the target age groups, characters with ASD on the screen may teach and inform children in ways to act and behave in an inclusive manner. Of course, herein there is a great potential in reducing bullying. Furthermore, feedback from the adult autism community on portrayals of characters with ASD is that although many do not familiarize with characters on screen, many others do. This may be of particular importance for children who are experiencing being different from other peers of similar age and thus having difficulty fitting in. Characters with autistic traits in TV-shows for children could be a

potential help for children with ASD to better understand their condition.

Finally, portrayals of characters with ASD in film and TV have been proposed for use in higher education, for example, in training of healthcare personnel (Conn and Bhugra 2012; Gabbard and Horowitz 2010; Safran 1998; Sartorius et al. 2010; Butler and Hyler 2005). However, to what extent portrayals of individuals with ASD are good or bad, or right or wrong, is not easy to determine since individual portrayals cannot capture the heterogeneity that resides within the autism spectrum. Therefore, although on-screen portrayals of autism can be a good point of departure for further discussion in educational settings (Conn and Bhugra 2012; Gramaglia et al. 2013; Nordahl-Hansen et al. 2017), competent educators with in-depth knowledge and experience with persons with ASD will be key as character portrayals can never capture real life. To make use of insights from actually autistic people would further strengthen the potential of usage of film and TV for educational purposes.

Behavioral analysis may be an effective way to analyze the function of scripting for some children. By analyzing the antecedents and consequences of scripting for children and adults with ASD, it may be possible to identify functional replacements for this behavior.

Synonyms

[Delayed echolalia](#); [Echolalia](#); [Parroting](#); [Scripting](#)

Definition

Repeating or reciting lines heard in TV shows, movies, songs, books, etc., is a common language pattern among children with ASD. "Movie talk" refers to repetitive speech taken from such a source, as opposed to a child's using novel, spontaneous language. Also known as scripting, the behavior involves reciting phrases or "chunks" of previously heard language and is synonymous with delayed echolalia. Some researchers believe "movie talk" is a form of self-stimulation used to tune others out or to work through a stressful or anxiety-producing moment. Others believe it is a means to initiate communication with others, or as a way to talk about an area of special interest.

Mu Rhythm

Beau Reilly
Psychiatry and Behavioral Sciences, University of
Washington, Seattle, WA, USA

Synonyms

μ ; μ rhythm; [Arciform rhythm](#)

Definition

Mu (μ) rhythm is a type of emitted brain wave that can be measured via electroencephalography (EEG). The mu rhythm frequency band is defined by activity falling between 8 and 13 Hz and

recorded by scalp electrodes over the sensorimotor cortex during waking neural activity. The mu rhythm band is posited to reflect the conductance of synchronized activity in large groupings of pyramidal neurons in the brain's motor cortex (Pfurtscheller et al. 1997) but has also been proposed to reflect activity of the mirror neuron system (Pineda 2005). The gradual loss of intensity and desynchronicity of neural activity, referred to as attenuation, is suggestive of an increased load on those specific cells and indicative of significant activation (Pfurtscheller et al. 1997). Attenuation of the mu rhythm has been noted during both the execution and observation of actions falling within one's behavioral repertoire. Physical movement in the body itself does not account for mu wave attenuation during an individual's observation of other's actions. The first neurological evidence of mu rhythm attenuation came from the work of Gastaut and Bert (1954) during observations of activity and response characteristics of subjects during motor tasks. It was noted that desynchronization of mu rhythm activity from centrally located scalp electrodes occurred not only during the active movements of the subjects, but also during subjects' passive observation of the same actions performed by others in the absence of any other overt motor activity. Because of the observed attenuation of the EEG mu rhythm during the execution and observation of actions, it has been proposed to reflect mirror neuron system activity (Pineda 2005).

Given the noted impairments in imitation, empathy, and social understanding in ASD and given that the mirror neuron system has been proposed to subserve many of these social cognitive abilities, the mu rhythm has been examined among ASD populations as an assessment of the mirror neuron system. Oberman and colleagues first found that children with ASD showed reduced attenuation of the EEG mu rhythm in response to the observation of simple actions (Oberman et al. 2005), providing support for the theory that the mirror neuron system is disrupted in ASD. Bernier, Dawson, Webb, and Murias (2007) replicated this finding in adults and observed that attenuation of the EEG mu rhythm is correlated with imitative abilities. This finding provided further support that the EEG mu rhythm may reflect activity of an

execution/observation matching system, such as the mirror neuron system and that this system may be related to imitation abilities. Although the existence of a human mirror neuron system is controversial and the literature contains conflicting findings regarding the presence of a disruption of the EEG mu rhythm in ASD, the EEG mu rhythm continues to be utilized in the investigation of action execution and observation among individuals with ASD.

MSEL:AGS; [Mullen scales of early learning, american guidance service edition](#)

Abbreviations

ELC Early learning composite

Description

The Mullen Scales of Early Learning: American Guidance Service Edition is an individually administered, multidomain measure of early development designed for children from birth to 68 months of age. It was developed by Eileen M. Mullen, Ed.D., and published in 1995. The MSEL:AGS consists of five individual scales: four cognitive scales that cover the age range from birth through 68 months (visual reception, fine motor, receptive language, and expressive language) and one gross motor scale that is administered from birth to 33 months. The four cognitive scales can be combined to produce an Early Learning Composite (ELC) that is said to represent “g” or “general intelligence.”

The MSEL:AGS was based on the author’s information processing and neurodevelopmental theories that conceptualize intelligence “as a network of interrelated but functionally distinct cognitive skills” (Manual, p. 1). By assessing these individual areas of development independently, the examiner can identify specific areas of strength and weakness. From the author’s perspective, this developmental profile can be used to aid in making diagnoses and also in developing strategies for individualized intervention plans (Manual, p. 33). Brief descriptions of each scale are included below.

The visual reception scale consists of 33 items. It assesses the child’s processing of visually presented information and includes tasks that require visual discrimination, categorization, and visual memory skills. While the scale is not completely “nonverbal,” it was designed to minimize the amount of language needed to understand instructions and give a response. Items range from visually fixating and tracking moving objects in early infancy to matching shapes, pictures, letters, and words and remembering visual forms for older children.

The fine motor scale consists of 30 items and (similar to visual reception) also requires minimal receptive and expressive language skills. Fine motor items measure visual-motor planning and

control, motor imitation, unilateral and bilateral manipulation of objects, and writing readiness skills. Individual items range from reflexively holding objects and bringing fist to mouth to stacking blocks, cutting with scissors, and copying shapes and letters with a pencil.

The receptive language scale consists of 33 items. This area focuses on the child’s ability to process linguistic input and assesses auditory comprehension and auditory memory skills. At the earliest age levels, the items assess the infant’s orienting to sounds and responding to voices. As the item difficulty increases, the young child is asked to follow verbal directions and respond to questions about spatial, color, size, length, and number concepts. Most items can be answered by pointing to a picture or handing over an object, but some of the more advanced items require brief spoken responses, such as answering general knowledge questions.

The expressive language scale consists of 28 items and involves the production of sounds/words and the use of auditory memory. Items range from vocalizing early vowel and cooing sounds in infancy to defining vocabulary words, repeating sentences, and solving verbal analogies.

The gross motor scale consists of 35 items. The manual states that this scale measures “central motor control and mobility” (p. 2) in a variety of positions that range from being held in the caregiver’s arms to the child being fully upright and independently walking, hopping, and running.

Time required for administration of the full MSEL:AGS varies by the child’s chronological age and ability level. The manual estimates administration takes approximately 15 min for 1-year-olds, 30 min for 4-year-olds, and 60 min for 5-year-olds. Directions include information on positioning infants up to 8–10 months of age and supplemental drawings. Some items can be scored based on parent report and therefore do not have to be directly observed. This is particularly helpful in expressive language items where it is often difficult to elicit vocalizations or spoken responses from young children in an unfamiliar setting. It is also permissible to vary the order of administration of both the scales and individual items within each scale and to readminister some items after a child has “warmed up.” For children

born prematurely (at or before 36 weeks gestation), scores may be calculated based on the child's corrected age up to 2 years.

The components of a complete MSEL:AGS include the Mullen test kit, stimulus booklet, record forms, and two manuals. The test kit contains most of the objects needed for item administration. However, some of these items lack the durability needed for young children (e.g., picture cards), and others present a potential choking hazard (e.g., small beads). The examiner must also supply a number of items not contained in the test kit, such as paper, cereal, large ball, colored tape or white chalk line, 6-in.-high bench, and stairs. Consequently, some preparation time is needed before each administration to insure that all the necessary materials are available.

The stimulus booklet contains black and white line drawings, primarily for use on visual matching, prewriting, receptive language, and expressive vocabulary tasks. On the record form, items are arranged in increasing order of difficulty for each domain. Arrows denote starting points for different ages, but examiners may use their judgment about which starting point to choose (e.g., the examiner may begin at an earlier start point for children with developmental delays). Brief descriptions are included for each item, along with cues for positioning infants and a scoring column. The MSEL:AGS Item Administration Book provides instructions for giving items in all five scales. For each item, this manual includes a list of needed materials, the recommended position for the younger infants (e.g., supported sitting, standing), administration directions, and scoring criteria. The instructions are generally understandable, particularly for professionals with experience in infancy and early childhood. The MSEL:AGS Manual provides information about the test's theoretical background, scale descriptions, general administration, scoring procedures, standardization and psychometric data, and raw score conversion tables. There are also three case studies provided to illustrate the use and interpretation of the MSEL:AGS.

Scoring for each scale varies from 1 point for a correct response to 0 points for an incorrect response on some items – to items where multiple

points can be earned for correctly completing component parts. Basal and ceiling rules are the same for each scale. A basal has been established for a scale when a child earns at least 1 point for each of three consecutive items beginning at a starting point. Testing continues until the child obtains scores of 0 points on three consecutive items. The sums of raw scores for each scale are used to compute derived scores that include T scores (mean = 50; SD = 10), percentile ranks, and age equivalents for each motor and cognitive scale and an Early Learning Composite (mean = 100; SD = 15) based on the four cognitive scales. Descriptive categories are also available (e.g., very high to very low).

Historical Background

The Mullen Scales of Early Learning: AGS Edition (1995) represents a revision of the original Mullen Scales (1992) and combines the Infant MSEL (1989) and the Preschool MSEL (1992) into a single test with norms that span the age range from birth through 68 months. The author, Eileen M. Mullen, Ed.D., developed the MSEL:AGS based on 30 years of clinical experience testing young children with developmental disabilities. She designed it to include multiple developmental domains based on the assumption that specific abilities mature at different rates in infants and young children. Viewed from this perspective, a test yielding only a global score would not provide information about patterns of cognitive strengths and weaknesses that can be used to plan interventions (Manual, p. 9). To arrive at the item sets for the current edition, item analyses were conducted using the Rasch one-parameter IRT model in order to obtain item difficulty estimates and indices of goodness of fit. A few items were dropped from the earlier versions, and the remaining items were sequenced by order of difficulty for the MSEL:AGS.

The structure of the individual scales was built on the author's theory of information processing where gross motor learning is considered to be the foundation for conceptual development in both visual and auditory modalities (Manual, p. 7).

Tasks from each of the four cognitive scales were analyzed in terms of the component processes required to perform them. Individual items in each scale are purported to target intrasensory (auditory or visual) processing or intersensory (auditory-visual) processing. More specifically, the visual reception and fine motor scales are designed to assess visual intrasensory processing, while the receptive language and expressive language scales are designed to assess auditory intrasensory processing. In addition, approximately half of the items on the receptive language scale are reported to assess auditory-visual intersensory processing. However, when one carefully analyzes the individual items, it is difficult to categorize them into purely one type of sensory processing since problem solutions often require multiple skills across multiple modalities. For example, solving the form-board task on the visual reception scale involves understanding the spoken directions (auditory), matching the shapes to their recesses (visual), using fine motor control to place the shapes into their respective holes (visual-motor), and so on.

The MSEL:AGS is the second most widely used measure of early development after the Bayley Scales of Infant and Toddler Development, Third Edition (2006) (Chawarska and Bearss 2008, p. 55). Before the Bayley III (2006) was redesigned to include cognitive, language (receptive and expressive communication), and motor (fine and gross motor) scales to replace the previous more global mental and motor scales, the Mullen Scales was frequently chosen for research studies because investigators wanted to be able to assess individual developmental domains (Klin et al. 2005). In addition, the relatively long age span (birth to 68 months) was very helpful for longitudinal projects (e.g., studies of the development of baby siblings of children with autism spectrum disorders).

Psychometric Data

The Mullen Scales was standardized on a sample of 1,849 children ranging in age from 2 days to 69 months and grouped into 16 age groups

ranging from 2-month age intervals from birth to 14 months to 5-month age intervals from 15 to 68 months. However, there were uneven numbers of children across the 16 age groups, varying from a low of 84 children at 11–12 months to a high of 156 children at 27–32 months. Standardization utilized 71 clinicians from a variety of disciplines and took place at more than 100 sites across the United States. It extended over an 8-year period and was conducted in two phases that covered different time periods and included different geographic regions. Phase 1 spanned June 1981 to February 1986 and included children from the Northeast. Phase 2 covered the period between December 1987 and April 1989 and included samples from the South, West, and North, and South Central areas of the United States. The standardization sample is described as “geographically diverse,” but it is not representative of the entire United States. For example, no children in the 1–14-month age range were recruited from the North/South Central region (Bradley-Johnson 1997). For the total sample, there were 48.7% females and 51.3% males which were very close to the US population estimates in 1990. However, there was some variability among the 16 age groups, e.g., males were overrepresented at 5–6 months (59.8%) and underrepresented at 27–32 months (43.6%). Parental consent and information on demographic variables (age, sex, race/ethnicity, father’s occupation, and urban/rural residence) were obtained for all children in the sample. Settings for testing included kindergarten, day care, nursery, and homes. All children in the sample were from homes where English was the primary language. It should also be noted that children with known physical or mental disabilities were excluded from the standardization sample.

Chapter 6 of the manual provides information about the reliability and validity of the MSEL:AGS. In terms of reliability, information is provided about internal consistency, test-retest reliability, and interscorer reliability. As a measure of internal consistency, the manual presents split-half reliability coefficients for the 16 age groups of the standardization sample (Manual, p. 56). Modified split-half internal consistency

coefficients were calculated for the five scales and the Early Learning Composite. The median values ranged from 0.75 to 0.83 for the scales and 0.91 for the ELC. However, four coefficients that were significantly lower than this range were omitted from the estimation of the median split-half coefficients. The author explained these omissions as being due to a ceiling effect on visual reception for the two oldest age groups and floor and ceiling effects on receptive language for the youngest and oldest age groups. With these same four age groups omitted, the standard error of measurement had medians ranging from 4.1 to 5.0 T score points for the scales and 4.5 standard score points for the ELC.

Test-retest reliability was reported in the manual for two samples based on administration of the original Mullen Scales of Early Learning. The first sample included 50 children from 1 to 24 months of age and the second sample included 47 children ranging from 25 to 56 months. The retest interval ranged from 1 to 2 weeks, with a mean test-retest interval of 11 days. For the younger sample, test-retest reliability was high for gross motor (0.96) and ranged from 0.82 to 0.85 for the cognitive scales. For the older sample (which did not include children from 57 to 68 months), the median stability coefficients ranged from 0.71 to 0.79. Interscorer reliability was reported to be high (0.91 to 0.99), but the number of scorers was not reported, and the sample only went up to 44 months.

The manual provides information about construct, criterion-related, and concurrent validity. Support for construct validity is provided by showing an increase in mean raw scores with increasing chronological age across all five scales. Intercorrelations and squared correlations were calculated for the five Mullen Scales for 5 age groups and the total standardization sample. Scales correlated with each other at low to moderate levels. This was interpreted as indicating both unique and shared variances. Exploratory factor analyses were also conducted for the five scales by 5 age groups. Only one factor was reportedly extracted at each age level and this was interpreted as supporting the Mullen ELC as a measure of "g" or general cognitive ability.

However, establishing construct validity for this measure is problematic because there is a lack of supportive data for the author's theory about intrasensory and intersensory processing leading to the identification of the child's learning style and its subsequent implications for remediation (Bradley-Johnson 1997).

Evidence for concurrent validity is based on three types of studies: (1) studies analyzed by the publisher correlating the MSEL:AGS with other measures such as the Bayley Scales of Infant Development (1969), Preschool Language Assessment (1979), and Peabody Developmental Motor Scales (1983), (2) studies reported in the manuals for the original Infant and Preschool Mullen Scales, and (3) studies reported in the research literature which primarily focused on differences between low-birth-weight and normal-birth-weight children. The MSEL:AGS correlated moderately well with the measures mentioned above – with higher correlations obtained when the specific Mullen scale more closely matched what the other instrument was purported to measure. For example, the receptive language scale on the Mullen correlated more highly with Auditory Comprehension on the Preschool Language Assessment (1979) than with the Bayley Scales (1969) Mental Development Index (that includes both verbal and nonverbal items).

Clinical Uses

The MSEL:AGS was designed for use by early childhood professionals working in a variety of settings, such as early intervention programs, preschool and kindergarten special education, universities, research laboratories, hospitals, rehabilitation centers, and private practice. The author described three major uses: (1) eligibility determination for early intervention and special education, (2) diagnostic assessment of children with special needs, and (3) individualized program planning (Manual, p. 5–6).

Under the Individuals with Disabilities Education Act (IDEA), infants and young children must meet specific eligibility criteria in order to qualify for early intervention or special education

services. The MSEL:AGS includes three of the five areas of functioning that must be assessed (i.e., physical (including gross and fine motor skills), cognition, and communication), but additional assessment with another measure is needed to cover personal-social and adaptive/self-help skills.

Because the MSEL:AGS includes five individual scales, it is useful in diagnostic assessments where clinicians are trying to determine whether children are progressing within the typical range of development or whether they are demonstrating significant delays in one or more areas of development. Determining a profile of strengths and weaknesses is essential in diagnostic assessments of children suspected to have a wide variety of disabilities, such as specific speech-language impairments, motor impairments (e.g., cerebral palsy), autism spectrum disorders, and global developmental delays. Clinicians also use patterns of performance to formulate recommendations for skills to address in intervention. However, as noted in the validity discussion above, the modality-specific approach to individualized program planning proposed in the MSEL:AGS has not been substantiated.

In summary, the MSEL:AGS has been widely used in developmental assessments of infants and young children. Both clinicians and researchers have appreciated the multiple domain structure and relatively broad age range. Although it is regularly used for diagnostic evaluations and eligibility determination for services, children with physical and mental disabilities were excluded from the standardization sample. In addition, much of the data used for standardization was gathered in the 1980s, so the norms are outdated, and there are no current plans to renorm this measure.

Multidisciplinary Evaluation

Sarah Melchior

School Psychologist, Services for Students with Autism Spectrum Disorders Montgomery County Public Schools, Silver Spring, MD, USA

Definition

Multidisciplinary evaluation refers to the process of gathering both formal and informal data from a variety of sources to determine whether a student is eligible for special education services and to provide information about his or her current levels of functioning. “Multidisciplinary” implies that evaluations will be conducted using a team approach in which a number of professionals (e.g.,

speech/language pathologists, occupational therapists, physical therapists, psychologists) gather assessment data about the student.

Historical Background

Prior to the enactment of Public Law 94-142, many students with disabilities were either not being served in public schools or were not receiving appropriate education services. Lack of adequate or appropriate assessments contributed to inaccurate labeling as well as education of students with disabilities. With the support of family associations, the federal government began to develop practices for children with disabilities in the 1950s and 1960s. The Elementary and Secondary Education Act (PL 89-10) and the State Schools Act (PL 89-313), both enacted in 1965, provided states with funding to improve the quality of education for students with disabilities. In 1975, the Education for All Handicapped Children Act, now referred to as IDEA (Individuals with Disabilities Education Act), guaranteed all students with disabilities the right to a free, appropriate public education. Another provision of IDEA included the need for a multidisciplinary assessment of students suspected of having a disability. Using a multidisciplinary approach to assessment, involving a variety of professionals with expertise in each area of need, contributed to more accurate diagnosis of children and the provision of more appropriate special education services for students with disabilities.

Current Knowledge

Developmentally based assessments including information about a child's cognitive, communication, social emotional, and adaptive skills are integral to the diagnosis and decision-making process for those suspected of having an autism spectrum disorder (ASD). Current research supports the need for evaluation of students suspected of having an ASD to take place within a framework that incorporates the knowledge and expertise of various disciplines. In addition to psychological

assessment and evaluation of the student's communication abilities, assessment data from other sources such as occupational therapy or physical therapy are also valuable. Outside of the school setting, pediatric, neurologic, and genetic assessment data are also important (Klin et al. 2005).

Autism spectrum disorders are characterized by atypical development in multiple areas, including cognitive development, communication abilities, social interactions, and play skills. A comprehensive approach to assessment that addresses all areas of concern is therefore necessary. To assess these multiple areas of functioning, a multidisciplinary team of professionals with expertise in these various areas must be involved in the assessment process (Noland and Gabriels 2004).

Future Directions

While a multidisciplinary approach to assessment is essential for children suspected of having an autism spectrum disorder, data from various professionals allows for multiple and, potentially, conflicting views of the child. In order to avoid this possibility, it is recommended that professionals operate in a transdisciplinary manner by which the team collaborates to present a single, coherent picture of the child's strengths and needs. By working together to present this single picture of the child, professionals are able to offer a more accurate view of the child and more fully address the impact of deficits in one area on other areas of functioning (Klin et al. 2005).

Multidisciplinary Training (TEACCH Component)

Lee Marcus¹ and Jemma Grindstaff²

¹TEACCH Autism Program, University of North Carolina, Chapel Hill, NC, USA

²Chapel Hill TEACCH Center, Carrboro, NC, USA

Definition

Training of professionals in approaches to intervention in autism has been an integral part of the TEACCH program since its inception in 1972. Training includes a wide range of topics in diagnosis, assessment, treatment, and education and occurs at TEACCH center throughout North Carolina and in multiple sites throughout North

Carolina, other states, and across the world. The training methodologies encompass lectures with audiovisual supports, activities designed for participant experiential learning, and hands-on experience with student trainers (i.e., children, adolescents, and adults with autism). The trainings are led by TEACCH directors (typically a Ph.D. licensed psychologist) and TEACCH staff therapists who have been working in the program for many years and have been trained in the various training models. Over the years, hundreds of professionals from across the world have been trained to be trainers, working as part of a TEACCH-led team.

Historical Background

When TEACCH was established as a statewide mandated program for serving individuals with autism and their families in 1972, there was virtually nothing known about service delivery, evidence-based practices, nor effective ways of preparing professionals to work with this population. There was little interest in autism as a field and more misunderstanding than accurate understanding of the condition. TEACCH grew out of a NIMH-funded project led by Eric Schopler and Robert Reichler which, on a small scale, documented effective ways of supporting children and their parents. With the legislation creating TEACCH at the University of North Carolina came the task of starting three diagnostic and treatment centers, training staff, and putting a model into practice. Simultaneously, 11 classrooms for students with autism were established, 10 of which were in public schools across North Carolina. Most, if not all, of these school districts had never educated a child with autism nor were prepared to recruit and train teachers. TEACCH took on this responsibility and organized a major training program for the new teachers as well as clinical staff at the three regional centers. The first trainings were lengthy, intensive, and complex and were based in a classroom setting with students with autism, a training team, and new teachers and assistant for 2 weeks. Over the course of the 2 weeks, along with lectures and group

discussions, trainees observed the training staff, learned the principles and practices of TEACCH, and gradually assumed responsibility for running the classroom during the second week. Staff to trainee ratio was high, close to one to one. This first model became a template for later variations of the training approach, based on the collaboration of trainer and trainee, experiential learning, and individualization. A major development in the model occurred about a decade later when a team of three TEACCH trainers led by Dr. Gary Mesibov, Director of TEACCH, adapted the earlier model with a less intense trainer to trainee ratio and shortening the process. The curriculum remained the same, but the training methods modified to effectively train more participants. Over the next three decades, there have been other modifications to the core structure of this training model and development of briefer basic training workshops that can reach larger audiences. The efficiency and accessibility of the trainings enable the program to be disseminated across the entire United States and dozens of countries across the world. Coordination of these training programs was led for much of this period by Dr. Roger Cox and implemented by TEACCH directors and staff across North Carolina.

Paralleling the professional service training models has been the center-based training of students at all levels of training and across many disciplines. The centerpiece of this training has been the Clinical Psychology Internship Program, started in 1974, and the Psychology Postdoctoral Training Program, started in the mid-1980s. The internship program is part of the UNC Department of Psychiatry's broad Psychology Internship Program, a program accredited by the American Psychological Association since 1962. Former TEACCH interns have gone onto prominence in the field of autism as leading researchers, clinicians, and program directors. Students receive intensive and comprehensive training in the diagnostic, assessment, and intervention methods used by TEACCH and regardless of their discipline or time commitment to their training experience receive exposure to the basic philosophy and practices of TEACCH, as well as to the field of autism as a whole.

A third area of training, also center-based, is placement of professionals from countries outside the United States who are interested in learning TEACCH methods and practices that can be applied to their home country. These international interns spend anywhere from a month to a year at a TEACCH center learning about all aspects of the program and most have returned to their countries and made significant contributions to services for individuals with autism, their families, and professionals.

Rationale or Underlying Theory

The rationale underlying TEACCH training is based on a key component of its mission statement:

The University of North Carolina TEACCH Autism Program creates and cultivates the development of exemplary community-based services, training programs, and research to enhance the quality of life for individuals with Autism Spectrum Disorder and their families.

TEACCH, while a North Carolina state agency, established to meet the needs of families in the state through direct services is also a significant part of the University of North Carolina and its School of Medicine. The dissemination of its knowledge and experience through training within North Carolina and around the world has been a primary activity since its inception in 1972.

Goals and Objectives

The goals and objectives of the TEACCH multidisciplinary training model are as follows:

1. To disseminate current knowledge, principles, and practices of the comprehensive TEACCH approach to the understanding and treatment of autism.
2. To provide state of the science training through effective and relevant ways to professionals in the field of autism in North Carolina, other states, and internationally.

3. To provide preservice education and training to undergraduate, graduate, and postdoctoral students across disciplines, including, but not limited to, psychology, psychiatry, speech pathology, education, social work, occupational therapy, pediatrics, and family medicine.
4. To provide experiential learning programs to students and professionals on specific tools and strategies, developed by TEACCH, such as structured teaching and the use of visual supports, working with parents as co-therapists, Child Autism Rating Scale (CARS2), Psychoeducational Profile – Third Edition (PEP-3), and TEACCH Transitional Assessment Profile (TTAP).

Treatment Participants

Historically, there have been three types of multidisciplinary training at TEACCH, as described above: in-service training of professionals, preservice training of students, and international interns. These types of training continue today, and each type tends to attract a different group of participants. The in-service training can be further divided into a five-day, intensive training model, which includes hands-on learning with student trainers, and other, more didactic workshops, typically of shorter duration (2–3 days) and with written scenarios to provide an experiential component. Thus far, two studies have examined these training models to evaluate their relative efficacy (Grindstaff 1998, 2000). In 1999, participants of the 5-day model were primarily special educators (55.4%), followed by speech language pathologists (10.9%), psychologists (8.9%), occupational therapists (5.0%), educational consultants (5.0%), parents (4.0%), teaching assistants (3.0%), school administrators (3.0%), and regular education teachers (1.0%). Participants in the comparison group were similar, with special educators in the majority (51.6%), followed by teaching assistants (16.1%), speech language pathologists (9.7%), regular education teachers (6.5%), parents (6.5%), school administrators (3.2%), psychologists (3.2%), and educational consultants (3.2%). An interesting shift has taken place in the last 12 years, such that, in the summer of 2011, the

group of participants in the five-day training model included fewer classroom teachers and a greater number of consultants who provide support to students with autism in regular education settings. Typically, the five-day model has attracted participants from across the United States, as well as a variety of foreign countries. The workshops have tended to attract a more local audience, specific to the region of North Carolina where the workshop has been held.

Preservice training includes students of all levels of training and from a variety of disciplines. Most often, these have been graduate students in psychology, speech language pathology, occupational therapy, and special education. Medical residents and fellows from pediatrics and psychiatry have also been an important subset. The greatest amount of training time and effort has been expended to develop the Clinical Psychology Internship. The TEACCH Intern spends at least 50% of his or her 12-month internship involved at TEACCH in autism-specific diagnosis, assessment, consultation, and intervention. Competition for this internship can be fierce, as applicants come from across the US and Canada; many of them will go on to take leadership positions in the field as researchers, clinicians, and program directors.

International interns have come from a variety of countries; many of them were first exposed to TEACCH principles during a five-day training held either here in the US or in their home country. Collaborations have been particularly rich with professionals from Japan, and more recently, from Sweden and Norway, leading to a greater percentage of international interns from those areas.

Treatment Procedures

The five-day training model is the most intense of the in-service training programs. Participants first attend lectures about the culture of autism and structured teaching to orient them for the week. Subsequently, they spend a small portion each day in lecture; the bulk of their learning takes place in small teams as they observe the TEACCH staff, develop activities for the student trainers, implement these activities with the student trainers, and

reflect on their collective experiences. Throughout the week, the principles of structured teaching are applied to the curriculum areas most relevant to students with autism: informal assessment, communication, independence, leisure skills, social engagement, and behavior management. Teams work with a different student trainer each day, ensuring that they have broad exposure to the diversity of the autism spectrum. The five student trainers are, of course, unique individuals, who also vary by age, cognitive ability, and severity of autism symptoms. Most training participants report that the opportunity to teach in the model classroom and interact with our student trainers is the most memorable component of this training experience.

Workshops vary considerably because they cover a wide range of topics. The Fundamentals Workshop introduces participants to the culture of autism and structured teaching, similar to the first 2 days of the five-day training model. Other workshops focus on the diagnosis of autism spectrum disorders, approaches to social skills instruction, and adapting curriculum for students in regular education, early intervention, and many others. New workshops are developed as the need arises. Most recently, workshops for parents have expanded to address their need for information about upcoming transitions: preparing for kindergarten, middle school, and adulthood. In all cases, an attempt is made to include a component of experiential learning – typically some type of written exercise or thought experiment that provides an opportunity for participants to apply what they are learning to their classroom, client, or child (in the case of parents). It is much less common to be able to provide the “live” interaction with student trainers that is so powerful during the five-day training.

Preservice training is often scheduled to coincide with the academic calendar. Residents or graduate students may observe for as little as 1 day; many future pediatricians, for example, spend a day observing a TEACCH diagnostic evaluation in order to increase their awareness of autism spectrum diagnoses and to facilitate appropriate referrals. Other trainees spend a month, a semester, or an academic year at their local

TEACCH center. Their experiences are tailored to meet their training goals and departmental expectations. As previously mentioned, the TEACCH psychology intern spends a 12-month year in the most intense preservice training. He or she may choose to spend an additional, fellowship year with TEACCH to develop greater independence as a clinician, participate in training efforts, and pursue research interests.

Training for international interns is also individualized, based on the expertise and interest of the intern. Many of these professionals are quite experienced in their discipline and with people with autism; however, they are seeking additional training specific to TEACCH principles and procedures. Often, they hope to acquire enough skill to implement TEACCH methodology in their home country, as well as the ability to communicate TEACCH principles to their colleagues. An intern may be responsible for establishing a new program or modifying an existing one to better reflect TEACCH principles. To that end, interns typically maintain an ongoing relationship with their TEACCH center to receive consultation and, sometimes, additional training.

Efficacy Information

Informal program evaluation takes place during every form of TEACCH training. Participants at all levels of training (in-service, preservice, and international interns) complete rating scales, answer written questions, and are generally encouraged to provide feedback to TEACCH staff. These responses have been universally positive. It is not uncommon for participants to report that their TEACCH training experience has proven more valuable than any other training program in which they have participated. Sometimes, participants also offer constructive criticism. Suggestions are always taken seriously and have sometimes resulted in a helpful revision to the delivery of the training model.

As mentioned above, there have been two formal evaluations of TEACCH’s in-service training efforts, designed to compare the relative efficacy of the five-day training model versus the two-day

Fundamentals Workshops (Grindstaff 1998, 2000). Outcomes were compared across the participants (1) knowledge of the training content, (2) attributions of controllability with regard to the extreme behavior of students with autism, (3) self-efficacy, (4) negative affect, and (5) use of structured teaching. Measures were completed at the very start of the respective training programs and again 6 weeks post-training. Results indicated that both training models were effective in increasing the participants' knowledge of the training content; however, neither model was associated with significant change in participants' attributions, self-efficacy, or affect. Participants in the five-day training model reported a significant increase in their use of structured teaching strategies back in their home environments; workshop participants did not. Grindstaff (2000) concluded that either training model could effectively convey the principles and philosophy of structured teaching but that only the five-day model (with its hands-on component) achieved the more elusive goal of helping participants apply structured teaching strategies to their classroom, clinic, or other work setting. Results from a small pilot study (Grindstaff 2000) indicated that the Structured Teaching Checklist could be used by a trained observer to evaluate the degree to which a classroom has successfully implemented the principles of structured teaching; this tool could prove useful as a more objective measure of training participants' use of structured teaching, as the initial studies relied solely on self-report.

Outcome Measurement

Since its inception, the Structured Teaching Checklist (STC; Grindstaff 2000) has been adapted for use as a standardized measure of TEACCH treatment fidelity (Hume et al. 2011). The TEACCH Fidelity Form has been demonstrated to have strong psychometric properties (e.g., inter-rater agreement, test-retest reliability, and internal consistency) and reliably discriminates between classrooms that adhere to the TEACCH model versus other treatment approaches (Hume et al. 2011). The TEACCH

Fidelity Form is specific to preschool classrooms, but perhaps, it could be elaborated to include classrooms for students at other stages of development, including a version for self-contained classrooms and one for students who are included in regular education settings. Once these additional versions are added, the TEACCH Fidelity Form will make an ideal measure for the effectiveness of TEACCH training.

Qualifications of Treatment Providers

For preservice training programs, there is typically a Ph.D. level psychologist who serves as the administrator and clinical director. Other trainers are often Masters level TEACCH staff who have served with the TEACCH program for a number of years and have demonstrated mastery of the principles of TEACCH training, as well as an ability to communicate effectively. There is a multistep process for becoming a TEACCH trainer that applies to TEACCH staff, as well as interested professionals from other organizations. First, the potential trainer must attend the five-day training model as a participant. He or she then returns as a "shadow trainer" – which means that he or she is apprenticed to an experienced trainer for the five days, with a focus on working with a specific student trainer, instead of the training participants. Shadow training is often repeated two or three times, until the potential trainer feels comfortable with a variety of student trainers. In the final stage of preparation, the potential trainer returns as a "reverse shadow" – which means that he or she now takes the lead not only with the student trainer but also with the training participants, with support from an experienced TEACCH trainer "behind the scenes." The potential trainer may continue as a "reverse shadow" until he or she is comfortable communicating about TEACCH principles and strategies, while also improvising with a student trainer. There is no specific time requirement for the completion of these stages of training, but the commitment is considerable.

In-service trainees and international interns receive supervision from the staff of their assigned

TEACCH center. This always includes the center director, a Ph.D. level psychologist, as well as the Masters level psychoeducational therapists, who come from a variety of disciplines. If there is a TEACCH staff member from the same discipline as the trainee, the two are often matched in a mentor-mentee relationship.

be in the category of autism, mental retardation, hearing impairment or deafness, visual impairment or blindness, emotional disturbance, speech and language impairment, orthopedic impairment, or health impairment. When referred to as multihandicapped, the person typically has disabilities that are severe enough to require intensive support to handle the functions of daily living. In education, the term “multiple disability” is used for students who have two or more disabilities that effect their ability to access education through traditional means. Children with multiple disabilities have a combination of affected areas such as speech and language, mobility, learning, intellectual functioning, sensory losses or dysfunctions, and behavior or social problems. Children are impacted in different ways, and the disabilities will vary in level of severity and how they manifest in everyday performance. Children with autism may be identified as having multiple disabilities if diagnosed with autism and intellectual disability. Educational support is often needed in the classroom, and some children will need support in all settings throughout their lives. Programming for these children will be based on the characteristics they display which will vary widely depending on the areas involved. Typically, the educational team includes a variety of professionals such as special education and regular education teachers, physical therapists, occupational therapists, speech and language pathologist, adaptive physical education teachers, nurses, paraprofessionals, psychologist, and possibly medical professionals.

Historical Background

The term “multi” means many or several and is used frequently in numerous contexts. The term handicap has a more involved history, some of which is not based on facts that can be substantiated. There is a story that is associated with the word “handicap” that leads people to believe it was first used when people with disabilities were allowed to beg in the streets with their “cap in hand.” There have been several attempts to dispel this myth but it seems to live on. The word does have a connection to a competitive sport dating

Multihandicapped

Michelle Lestrud
The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Definition

Multihandicapped refers to a person that has more than one disabling condition. The disability may

back to 1650s but was not used in conjunction with a person with a disability until the early 1900s. As the term “handicap” evolved, it now refers to a person with a disability. The term alone does not give information as to what type of disability a person may have. Once multi was added to handicap, it came to have the meaning we know today of more than one disabling condition which makes functioning in daily activities more difficult when compared to a person without the disabilities.

locus) – this can imply multiple disease variants acting simultaneously in each patient, or single mutations in each patient, but in different genes (unsure of this definition). Tuberous sclerosis, for example, can be caused by mutations in either TSC1 or TSC2 (EntrezGene, OMIM). Coronary artery disease, on the other hand, could be due to more than one gene working in concert (e.g., Saade et al. 2011).

Some ASD cases are attributable to specific chromosomal abnormalities, or to deletions/rearrangements known to induce autism (when these rearrangements confer other symptoms and phenotypes in addition to autism, they are known as “syndromic” autism). No one cause has been found that explains more than 1–2% of autism cases (gross chromosomal abnormalities). A recent review summarized that taken together, all gross chromosomal abnormalities, all syndromes associated with autism, disruptions to known autism loci (e.g., SHANK3), and rare variants in candidate genes account for only 12–17% of autism cases, meaning that the majority of autism cases remain unclear with regard to specific genetic etiology (Buxbaum 2009). Another estimate put it at 5–15% (Pinto et al. 2010). Additionally, even syndromic causes that associate strongly with autism, such as fragile X syndrome, are not completely sufficient to induce autism; there exist fragile X patients who do not present with autism or ASD. Though some cases are largely influenced by highly deleterious single-gene mutations, even these are likely modulated by mutations in other genes. Similar ASD phenotypes need not necessarily involve the exact same genes in each case; it is possible that many autism cases can be caused by any one of a number of combinations of different genes in neurological pathways.

Multilocus Genetic Models

John D. Murdoch
Child Study Center, Yale University School of
Medicine, New Haven, CT, USA

Definition

A multilocus genetic model means that a given phenotypic outcome is influenced by multiple genes (an individual gene is referred to as a

Historical Background

Modern understanding of genetic inheritance is widely accepted to have begun with Gregor Mendel and his experiments with trait inheritance in garden peas. What we call Mendelian inheritance is the simplest form of transmission of genetic information: one gene, two or more alleles, a

relationship between the alleles (dominant, recessive, codominant, incompletely dominant, etc.). Sex-linked traits modify the situation somewhat; disruptive mutations on the X-chromosome that may be recessive in females, being offset by the healthy X-chromosome, can be deleterious in males, who have only one X-chromosome. Multilocus disease models, while always theoretically possible, became more discussed in the late 1970s and early 1980s, particularly in the context of autoimmune diseases (see Rotter and Landaw 1984). A consensus for autism as a primarily genetic disorder did not fully emerge until the late 1980s to mid-1990s (Bailey et al. 1995; Bolton et al. 1994; Smalley et al. 1988; Szatmari et al. 1998), and fairly quickly, it became apparent that single-gene inheritance models did not explain most autism cases (e.g., Jorde et al. 1991). An early multilocus model of family recurrence in autism determined that 3 interacting genes, in a range of 2–10, best accounted for their data. Another multilocus model was put forth by Risch et al. in 1999. They concluded that on the basis of evidence seen in 97 affected sibling pairs (ASPs; both siblings diagnosed with autism) and 51 discordant sibling pairs (DSPs; one sibling had autism and one was unaffected), as well as follow-up in 50 ASPs and 29 DSPs, one or a few mutated gene loci in a given sibling pair did not adequately explain the increase in shared DNA inheritance between the affected siblings relative to the discordant siblings. On the basis of the families they assessed, the authors determined that a model based on 15 or more interacting gene loci explained their data better than a model with 10 or fewer gene loci (Risch et al. 1999).

As autism genetic models were being debated, a broader debate was emerging in the genetic field about the etiology of complex (multigenic), relatively common diseases. The common disease-common variant theory held that for a disease to remain relatively common in the population, the mutations being inherited must not be damaging enough, on their own, to reduce reproductive success of those carrying them, and therefore more severe common disease phenotypes must be due to the interaction of

many common variants, each of a small effect size (contributing a small amount to the disease phenotype, and not disruptive enough to reduce reproductive fitness on its own) but significant enough when inherited in combination to induce a disease state. In contrast, the common disease-rare variant theory held that multiple rare variants, each of larger effect (more disruptive), were sufficient to cause common diseases. These deleterious rare variants would in theory be more prone to reducing reproductive success, but if many of these rare mutations were being generated spontaneously (*de novo*) rather than inherited from parents, in a large enough number of genes, it could explain the baseline prevalence of even severely disruptive alleles.

As evidence accumulated that methodologies driven by the common disease-common variant assumption (exemplified by genome-wide association studies) could account for only a modest proportion of common complex disorders, the common disease-rare variant theory gained traction in research on these disorders. Autism in particular was poorly accounted for by genetic methods seeking to associate common variation with the disorder (e.g., Anney et al. 2010; Curran et al. 2011; Hirschhorn and Gajdos 2011). A few implicated genes and regions were replicated in other studies (e.g., *MET*, *CNTNAP2*, and *5p14.1*) (Alarcon et al. 2008; Arking et al. 2008; Campbell et al. 2010; Jackson et al. 2009; Sousa et al. 2009; Wang et al. 2009; Weiss et al. 2009); however, common variants overall likely account for a small proportion of autism heritability (Pinto et al. 2010). Rare copy number variants (Bucan et al. 2009; Pinto et al. 2010; Sanders et al. 2011) began to gain attention as several studies suggested a role in autism. With the emergence of dense genome-wide marker SNP genotyping as well as exome sequencing, and follow-ups on these studies, evidence accumulated for a multihit etiology (i.e., mutations in multiple genes in the same person) in at least some autism cases, for example, *FOXP1* and *CNTNAP2* (O’Roak et al. 2011), *CNTNAP5* and *DOCK4* (Pagnamenta et al. 2010), and *DMD* and *TRPM3* (Pagnamenta et al. 2011). The emerging methods allow us to concretely demonstrate the multilocus

model in patient data, beyond just discussing its theoretical fit to the existing data.

Current Knowledge

The current state of the field is that large-scale chromosome rearrangements, genetic syndromes, and the few known definitively autism-associated loci (e.g., SHANK3, 15.q11-13) are of large effect size, but account for a modest proportion of total autism cases, and likely in conjunction with other genes in a given case. The majority of cases are likewise caused by mutations in a variety of genes, the list of which researchers are constantly working to validate, corroborate, and expand. The challenge is no longer to demonstrate the validity of the theoretical underpinnings of the multilocus model but to use more and more precise genetic tools to establish exactly what genes, and perhaps networks of genes (e.g., gene families or biological pathways), are involved in autism.

Future Directions

As the prices of whole-exome and whole-genome resequencing continue to drop, these technologies, combined with wider- and wider scale genotyping of SNP markers across the entire genome, it will be possible to analyze patients with autism at a finer and finer scale, potentially uncovering new viable candidate genes and contributing mutations, and strengthening or weakening the cases for existing candidate genes as we examine larger numbers of people in greater detail than ever before. These thorough analyses of individuals and their families represent the emerging present and near future in autism research.

Multiple Complex (or Multiplex) Developmental Disorder

Jan Rutger Van der Gaag

Department of Psychiatry and Karakter
University Center for Child and Adolescent
Psychiatry, Radboud University Medical Centre,
Utrecht, Netherlands
Stradina University of Riga, Riga, Latvia

Definition

The greatly missed Cohen et al. (1986) thought we should try and specify subgroups within the so-called not otherwise specified areas within the broader category of pervasive developmental disorders. From cluster analyses of a big group of individuals with atypical development, within the area on the fringe of autistic disorders, two categories emerged: Asperger's disorder (that was added to DSM IV 1994) and the group so-called multiplex developmental disorders (later renamed multiple complex developmental disorder to avoid confusion with MDD – “major depressive” disorder).

In this entry, this “heuristic” category is described.

Historical Background

Along with defined categories from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (DSM-IV-TR) includes so-called Not Otherwise Specified (NOS) categories meant for lesser variants or borderline conditions to the clearly defined cases.

The NOS subcategory for pervasive developmental disorder (PDD-NOS) was introduced in DSM-III-R (1986). Cohen et al. (1986) were concerned that having only two categories for autism in DSM-III-R would be too few to provide a more fine-tuned description of subgroups within what is now commonly named the autistic spectrum. These subgroups had been identified by

on-cluster analyses on large groups of children with “atypical” behavior (Prior et al. 1975; Dahl et al. 1986).

Cohen et al. suggested that two new categories should be introduced in DSM-IV. The first one would be Asperger’s disorder (Asperger 1944; Wing 1981), referring to individuals with developmental problems in the areas of social reciprocity, communication, and rigid and restricted patterns of behavior. These individuals differed from the classical Kanner autism in that they developed language at typical stages (yet not the adequate pragmatics), and they had motor clumsiness and intellectual preoccupations more than motor stereotypies. This category was finally included in DSM-IV, but the criteria did not include many of the features Asperger actually described (Miller and Ozonoff 1997).

The second proposal (Cohen et al. 1986, 1991) on multiple complex developmental disorders (MCDD) was not included in DSM-IV. It was a heuristic proposal aimed at promoting research on a category well known in clinical practice (Green and Jones 1998) and clearly emerging as a distinct cluster in the analysis of the children with atypical developmental (Dahl et al. 1986). These children had previously been described under different diagnostic labels, including “borderline children (Bemporad et al. 1982; Pine 1974; Vela et al. 1983), schizoid personality in childhood (Wolff 2003), and schizotypal children (Nagy and Szatmari 1986). Ironically, it had been included in DSM-III (American Psychiatric Association [APA] 1980) with the label “Childhood-Onset Pervasive Developmental Disorder” but, for reasons that are not clear, was not continued into DSM-III-R and thus not considered in DSM-IV.

All these labels recognized children who could be placed “in the borderlands of autism.” They share with more classically autistic children a lack of social sensitivity and empathy, but yet differ importantly from autistic children. Where children with “classic Kanner autism” lack imagination, these atypical children tend to get carried away by a far too-vivid imagination that blurs their reality testing.

Current Knowledge

The defining criteria for MCDD include (1) consistently impaired social behavior and sensitivity, (2) impaired regulation of affective state, and (3) impaired cognitive processing “thinking disorder.”

The discriminative potential of these criteria in categorizing these children reaches sensitivity and specificity levels comparable to those for autistic disorder (Buitelaar and van der Gaag 1998) (Table 1). The face validity of the concept was demonstrated in a series of independent studies (Towbin et al. 1993; Van der Gaag et al. 1995). The predictive validity is high (Van der Gaag 1993). There is longitudinal persistence of symptoms in the area of development of social reciprocity and thinking disorders. The extreme problems in the regulation of affective states are less prominent in adolescents and adults. There is a marked shift toward symptoms from the schizophrenia spectrum in adults, with up to 17% of the cases meeting criteria of schizophrenia after one or several psychotic episodes and over 60%

Multiple Complex (or Multiplex) Developmental Disorder, Table 1 Criteria for multiple complex developmental disorder (Cohen et al. 1994 – van der Gaag et al. 2005)

- | |
|---|
| 1. Impaired regulation of states of mind and anxieties |
| A. Unusual or peculiar fears and phobias or frequent idiosyncratic or bizarre anxiety reactions |
| B. Recurrent panic episodes or flooding with anxiety |
| C. Episodes of behavioral disorganization punctuated by markedly immature, primitive, or violent behavior |
| 2. Impaired social behavior |
| A. Social disinterest, detachment, avoidance, or withdrawal |
| B. Markedly disturbed and/or ambivalent attachments |
| 3. The presence of thought disorder |
| A. Irrationality, magical thinking, sudden intrusion on normal thought processes, bizarre ideas, neologisms, or repetitions of nonsense words |
| B. Perplexity and easy confusability |
| C. Overvalued ideas, including fantasies of omnipotence, paranoid preoccupations, overengagement with fantasy figures, and referential ideation |

Note. A total of five (or more) items from (1), (2), and (3), with at least one item from (1), one item from (2), and one item from (3) (Buitelaar and van der Gaag 1998)

meeting the criteria for schizoid or schizotypal personality disorder (Van Engeland and Van der Gaag 1994). Other differences come from studies on the stress-regulation characteristics in the MCDD group (Jansen et al. 2003; Kemner et al. 1999) that show marked differences in these areas between individuals with autistic disorder and individuals with MCDD who, on these dimensions, are more similar to adults within the schizophrenia spectrum. The third characteristic of MCDD children includes “disordered thinking,” which is commonly thought to be specific to schizophrenia.

Future Directions

In DSM V, the search for specific subgroups will be dropped. But research should be pursued along the dimensions of impaired regulation of affective states and thought disorder in individuals with autism spectrum disorders. This research will be important for a well-suited guidance and treatment program and to explore the boundaries between autism spectrum and schizophrenia spectrum disorders as apparently at least a portion of high functioning individuals with autism spectrum disorders are at risk of having psychotic episodes in their adult life and for developing schizophrenia and/or addictive behavior.

Synonyms

Multiple exemplar instruction (MEI); General case teaching, general case instruction

Definition

Multiple exemplar training (MET), which is also known as multiple exemplar instruction or general case teaching, is a term in applied behavior analysis (ABA) for the use of related stimuli samples during instruction to increase a person's ability to respond to novel, untrained stimuli (Greer et al. 2005). For example, teaching a child to say “lime” when shown various examples of limes (i.e., photographs, illustrations, physical objects) increases the likelihood that the child will be able to say “lime” when he/she is later shown an untrained image of a lime that possesses some characteristics related to previously taught exemplars. The ability

for an individual to deduce that two similar stimuli are related or the same, such as labeling untrained images of limes, is crucial to engage in generative behavior (the ability to “generate” novel behaviors based on previously learned stimuli). It's worth noting that learning both physical and arbitrary relations may contribute to generative behaviors. That is, like learning to label a “lime,” one can also learn to label a lime with arbitrary labels, such that when asked, “what shape is this?” or “what color is this fruit?”, one answers “round/green.” Successful generative responses may occur when interpretation of context-specific stimuli occurs, in which many cases involve a combination of both physical and arbitrary conditions such that when one is asked, “give me a round, green, fruit,” one can deduce that the speaker is likely asking for a lime (Holth 2017).

The term “multiple exemplar training” was first coined by Hughes and Rusch (1989) in a study that taught people with intellectual disabilities to solve work-related problems using MET and self-instruction (Holth 2017). Although the term MET did not appear until 1989, there are multiple records in which MET teaching strategies were implemented before the term was conceived. For instance, a study in 1967 noted an increase in correct responding to other, untrained imitations after teaching and reinforcing various models of imitation (Baer et al. 1967). The use of MET to teach children with autism spectrum disorder (ASD) first emerged in a study that taught four high school students with ASD to initiate and sustain social interactions with neurotypical developing peers through a “multiple exemplar strategy” (Breen et al. 1985). People with autism often have difficulty engaging in generative behaviors which tends to result in limited responses for a wide variety of situations (Schnell et al. 2018). Because the use of generative behaviors is imperative for adapting to an environment with varying stimuli, and given that people with ASD often have difficulty naturally learning to respond to varying stimuli, MET is often used as a teaching strategy in ABA to assist people with ASD learn to emit generative behaviors and promote the maintenance of skills (Greer et al. 2005).

MET studies have noted the emergence of two MET teaching variations, serial MET (S-MET), in

which exemplars are introduced one at a time, and concurrent MET (C-MET), in which a group of exemplars are all introduced at the same time (Schnell et al. 2018). Although MET studies have successfully taught a variety of skills and related generative responses, such as expressive labeling, imitation, listener responding, behavioral variability, matching, social behavior, and responding to wh-questions (Holth 2017; Schnell et al. 2018), contrasting findings exist between studies regarding which type of MET strategy is more efficient (Schnell et al. 2018). A study by Schnell, Vladescu, Kodak, and Nottingham compared the mean training time, total training time, exposure to mastery, and training sessions to mastery between S-MET and C-MET when teaching expressive labeling and observed that S-MET had the lowest mean training time and total training time, which differed from previous studies that indicated C-MET is a more efficient strategy (Schnell et al. 2018). Be that as it may, more research should be conducted to replicate the efficacy of MET teaching variations since there are currently two studies that have examined the efficacy of MET regarding expressive labeling tasks. Researchers also stressed the importance of expanding MET efficacy research for teaching other tasks, such as comparing efficacy of S-MET and C-MET when applied to imitation tasks, listener responding tasks, and other types of behaviors. In addition, future studies should focus on evaluating whether MET teaching strategies are more effective when individualized to the students. For example, Schnell et al. (2018) noted that, despite S-MET had the lowest mean training time, efficiency varied between students and across teaching strategies. In other words, all the participants were able to master exemplars the fastest with the use of S-MET, but each participant's performance varied in both time and number of exposures to mastery.

Multiple Exemplar Video Modeling and Unscripted Social Communication

Definition

Multiple exemplar video modeling involves the creation and presentation of several videos depicting multiple response options and varied stimuli (e.g., setting, materials) of desired

behaviors to promote response and stimulus generalization.

Historical Background

Based on social learning theory (Bandura 1977), video modeling (VM) is a highly effective intervention used to teach new behaviors through imitation of a model presented via video technology. VM is considered an evidence-based practice by the National Autism Center (NAC 2015) and the National Professional Development Center on Autism Spectrum Disorder (NPDC; Wong et al. 2015). Video modeling researchers have reported the following inherent factors in VM that may produce positive feasibility and acceptability: (a) although recording and editing videos can take time, once these materials are made, their repeated use is infinite; (b) the increasing availability and usability of digital video equipment increase their probable use (Ayres and Langone 2005); (c) videos are often presented in socially acceptable technologies such as iPods and iPads that do not limit the individual's opportunities to interact with peers (Shane et al. 2012); and (d) researchers have also reported that VM is cost- and time-effective (Charlop-Christy et al. 2000). Though none of these factors have been empirically evaluated, they may influence the likelihood that VM interventions are delivered in natural settings (e.g., school, home, and community), which may contribute to the long-term effectiveness of VM.

Researchers and practitioners have evaluated and implemented VM to teach scripted play verbalizations to children with autism spectrum disorder (D'Ateno et al. 2003; MacDonald et al. 2005; MacManus et al. 2015) and have involved typically developing peers as part of the intervention (Joint Video Modeling; Dueñas et al. 2019; MacDonald et al. 2009; Maione and Mirenda 2006). Despite positive social communication outcomes for children with ASD reported in the extant VM literature, little is known about the generality of social communication repertoires acquired following brief periods of VM exposure, as few studies measure generalization effects

(Bellini and Akullian 2007; Goldstein et al. 2014; Sutton et al. 2018). This is an important direction for future research as the aim of social communication interventions for children with ASD is the generalization of acquired social communication behaviors across people, settings, and contexts that have social and applied value. That is, the degree to which a skill generalizes can have crucial implications over the utility of the skill for a child with ASD.

For individuals with ASD who struggle to generalize acquired social communication, it is necessary to program generalization in instructional or treatment arrangements. There are numerous recommended strategies for promoting generalization, primarily stemming from reviews of behavior-analytic literature (Haring 1988; Stokes and Baer 1977; Stokes and Osnes 1989). One of these strategies is to program multiple exemplars. Programming various exemplars involves providing various examples for responding until untrained responses emerge.

Current Knowledge

Preliminary research in VM has shown that varying the social communication behaviors modeled in videos during social interactions may evoke several potential responses when presented with similar contexts (see Dueñas et al. 2019; MacManus et al. 2015; Maione and Mirenda 2006; Plavnick and Dueñas 2018). Programming multiple exemplars is an instructional strategy that may promote the acquisition of repertoires as opposed to rote responses (Stokes and Baer 1977). This focus may help children with ASD to demonstrate more natural social communication across varied contexts (Kasari et al. 2016). Novel social communication skills are a desired focus of social interactions between children with ASD and their peers, as predictability and rote responding are less typical among children who are not diagnosed with ASD.

Video modeling is an intervention that can be used for programming several generalization strategies that promote response and stimulus generalization. For example, recording several

videos to model multiple response options for promoting response generalization (i.e., multiple exemplar video modeling). Dueñas et al. (2019) demonstrated that multiple exemplar video modeling was a promising intervention for teaching scripted and *unscripted* social communication during pretend play with typically developing peers in an inclusive early childhood setting. This multicomponent intervention combined video modeling with peer-mediated intervention. Video models were presented to both children prior to play sessions as a way to prompt children to engage in verbalizations during pretend play interactions. The procedure involved an initial invitation from the typically developing peer to invite the child with ASD to play. The children were seated at a small table side by side according to the roles they were imitating in the video. The iPad was presented on the table directly in the middle of both children, and they were exposed to the audio in the video using headphones with a splitter. The video was shown twice, and the researcher ensured their bodies were positioned in front of the screen and their faces were directed to the screen. Three video exemplars were rotated across sessions to ensure equal number of presentations for each video exemplar. The children were instructed to “Do and say what you saw in the video” and were given 3 min to play with the toys that were set up at the table. For a sample of video scripts, see Table 1. Although children with ASD increased scripted and unscripted verbalizations toward peers, participants with ASD in the study all responded differently to the intervention. Dueñas et al. (2019) hypothesized that as children with ASD began to deviate from scripts, typically developing peers struggled to respond consistently.

Researchers can also record various people to model social behaviors (e.g., peers, teachers, and parents), using portable electronic devices that optimize implementation across settings (e.g., home, community, classrooms). For example, in Playnick and Dueñas (2018), researchers evaluated the effects of video-based group instruction on spontaneous social questions and comments of four adolescents with ASD. The researchers created three variations of video clips for five

Multiple Exemplar Video Modeling and Unscripted Social Communication, Table 1 Sample video script

Objects	Scripted play actions	Scripted verbalizations
Mom bunny	Holds bunny and jumps up	“Dinner’s ready”
Sister bunny	Holds bunny and moves downstairs	“I’m coming”
Mom bunny	Moves bunny to table	“Made your favorite”
Sister bunny	Sits bunny on chair	“What is it?”
Mom bunny	Has bunny put two plates on table	“It’s pizza”
Sister bunny	Has bunny knock down table	“No, my pizza”
Mom bunny	Has bunny set table	“I got it”
Sister bunny	Moves bunny to chair	“Thanks, mom”

different social behaviors. The videos varied in terms of models, materials used, and the vocal statements modeled in the videos. All participants demonstrated an increase in spontaneous social questions and comments.

Future Directions

Although preliminary research shows promise in promoting generalized responding, future research is needed to determine whether a relationship exists between multiple exemplar video modeling and novel social communication. That is, precise procedures that lead to novel social communication continue to be unknown. Specifically, whether typically developing peer involvement, multiple exemplar videos, or both led to children with ASD’s deviation from scripts. In addition, when designing multiple exemplar video modeling procedures, several questions remain, for example, What is the ideal number of video exemplars?, What is the amount of video exposure needed and is this skills- and/or student-dependent?, and Are there prerequisite or language skills of children with ASD that make them ideal candidates for this intervention?

Multiplex-Simplex Comparisons

Stephan Sanders
Child Study Center, Yale University, New Haven,
CT, USA

Definition

“Multiplex” refers to families in which multiple individuals are affected by a specific disease, while “simplex” refers to families in which only a single individual has a specific disease. This distinction is important when designing a study to identify risk factors for ASD, as multiplex families are thought to be more likely to have shared risk factors (i.e., inherited risk), while simplex families are more likely to show de novo genetic risks. Accordingly major collections of ASD samples for genetic analysis are often designed to enrich for specific types of families, such as the Autism Genetic Research Exchange (AGRE) with many multiplex families and the

Simons Simplex Collection (SSC) with exclusively simplex families.

Categorizing families as being multiplex or simplex can be difficult. For example, the presence of only a single affected individual among siblings may not truly reflect the underlying genetic architecture of that family. For example, an unaffected sibling could simply not have inherited a transmitted risk factor that is still present in the parents (and might be transmitted to the next sibling to be born). Alternatively, it is common to observe individuals carrying known genetic risk variants for ASD without showing clinical evidence of autism. The objective of making the distinction is to determine whether shared or unique risk factors are most likely to account for disease. Since ASD is likely to be the combination of many genetic and environmental risk factors, it is probable that many individuals with ASD have a combination of both shared and unique risk factors. The distinction between multiplex and simplex families is therefore best considered as a continuous spectrum that enriches for shared or unique risk factors at each respective extreme.

The distinction between multiplex and simplex families also has bearing on the risk of a further child having ASD. This risk is considerably higher in families with a previous child with ASD, especially if more than one child is affected (Ozonoff et al. 2011).

Music Therapy

Jinah Kim

Department of Creative Arts Therapy, College of Cultural Convergence, Jeonju University, Jeonju, Jeollabukdo, Republic of Korea

Definition

Music therapy uses musical activities such as singing, playing instruments, improvisation, and music listening to promote interaction between the therapist and the client and to meet the client's therapeutic needs. American Music Therapy Association (2005) defined music therapy as "the clinical and evidence-based use of music interventions to accomplish individualized goals within a therapeutic relationship by a credentialed professional who has completed an approved music therapy program."

There are many different approaches in music therapy. In a broad sense, music therapy methods can be divided into either active or receptive music therapy, depending on whether the client is actively involved in live music-making processes with the therapist or the client is involved in a preselected music listening using either a recorded music or a live performance. In active, especially the improvisational music therapy intervention, interactive use of live and spontaneous music-making process between the therapist and the client, the client is encouraged and facilitated.

Therefore, musical-therapeutic context evolves through musical interaction between the therapist and the client here and now and moment by moment. In receptive music therapy intervention, music is selected or precomposed based on the preference and needs of the client to accomplish certain therapeutic outcomes for individuals with autism spectrum disorders (ASD). Research evidences have indicated that both active and receptive music therapy methods are found to be effective at facilitating and improving communication and social interaction skills and to modify certain behaviors of individuals with ASD (Accordino et al. 2007; Geretsegger et al. 2014; Simpson and Keen 2011). In clinical practice, music therapists tend to use the method that serves their client's individual needs, sometimes resulting in eclectic approaches.

Historical Background

There have been various approaches in music therapy, depending on the different philosophies and principles of the founder of each music therapy approach in different clinical settings. Early music therapy pioneers such as Juliette Alvin, Paul Nordoff, and Clive Robbins worked with children with special needs including autism from the 1950s. These early pioneers used live interactive music (improvisation) to engage the children with ASD and to address their difficulties in communication and social interaction (Alvin 1978; Nordoff and Robbins 1971). Now, there are many music therapists working within the improvisational model of music therapy worldwide, especially in the UK and Europe.

Following are four internationally known improvisational models of music therapy:

1. Free improvisation therapy founded and developed by Juliette Alvin
2. Creative music therapy founded and developed by Paul Nordoff and Clive Robbins
3. Analytically oriented music therapy founded and developed by Mary Priestley
4. Interactive music therapy founded and developed by Amelia Oldfield

All four approaches above have been mainly developed in the UK.

Another significant approach in music therapy has been behavioral modification model of music therapy that was chiefly developed in the USA and is still the primary music therapy intervention in the USA. The influence of behavioral modification model of music therapy is also prevalent worldwide especially for children with special needs including autism.

Simpson and Keen (2011) has identified composed songs and improvisation as the predominant music therapy techniques used for children with ASD. Research evidence indicated that behavioral music therapy and improvisational music therapy all work well with individuals with ASD (Geretsegger et al. 2014; Kaplan and Steele 2005; Simpson and Keen 2011).

Rationale or Underlying Theory

Music is often described as a universal or emotive language. Music therapists have attributed this mainly due to its power to reach and affect human emotions. No matter how disabled a person can be, anyone can respond to music, and musical responses are innate ability deeply engrained in human nature (Alvin 1978; Kim et al. 2009; Nordoff and Robbins 1971). Moreover, musical experiences are often intrinsically joyful and interesting. Music often inspires, motivates, and brings people together even when they are total strangers. Kim and her colleagues (2009) claim: "Music acts as an essentially emotional, relational and motivational medium when, in music therapy, it is purposefully created to engender 'interpersonal relatedness' by employing a well-measured systematic intervention." Thaut (1987) found that children with autism engaged significantly more time with the music than age-matched typically developing children. He also analyzed musical responsiveness of children with autism, and that of children without autism through music improvisation they played, and found no significant difference in musical responsiveness between them. The results indicated

intact musical responsiveness and musical aptitude in children with ASD. Clinical implication of these findings suggests significant therapeutic potential in music that can be used in helping individuals with ASD in everyday life.

Music can be an excellent medium for emotional communication and social interaction for individuals who cannot easily assimilate the conventional ways of human communication and interaction. Instead of verbal exchange, nonverbal aspects of music such as playing simple instruments, vocalizing, and listening to music can provide an alternative way of communicating and engaging the individuals with ASD and others without ASD. Music can be utilized to teach new skills (Buday 1995; Kern and Aldridge 2006), to help children with ASD perceive and recognize specific emotions (Katagiri 2009), and to modify children's behaviors (Brownell 2002; Kern et al. 2007) in a certain direction that can be helpful and adaptable in everyday life. As children with ASD are reported to respond better to songs than spoken words, a music therapist might create original songs (Brownell 2002; Katagiri 2009; Kern and Aldridge 2006), or lyrics with familiar melody (Kern et al. 2007) about a specific behavior, and use these songs with children with ASD with specific therapeutic goals in mind including speech and language development.

Goals and Objectives

Goals and objectives of music therapy intervention for individuals with ASD are usually established through music therapy assessment. Music therapists assess the individual's needs, especially the domains of emotional, communicative, behavioral, and social responses and cognitive skills for individuals with ASD. Systematic review of music therapy literature has indicated primary goal areas in music therapy intervention: (1) to promote socialization, (2) to increase communication and language skills, and (3) to modify maladaptive behaviors (Accordino et al. 2007; Geretsegger et al. 2014; Simpson and Keen 2011). Once broad goals are set up, the therapist

identifies specific objectives that are observable and measurable such as “when therapist sings a ‘hello song’ in the beginning of the session, child will look at the direction of therapist 30% of the time.” Objectives of music therapy will change in time as therapy progresses. As autism spectrum disorders are complex neurodevelopmental disorders showing variety and individuality across all ages and abilities, therapeutic objectives for individuals with ASD varies a lot from person to person and stage of each therapy process. Musical responses of the brain is not localized in one area, but known to be widespread. Therefore music has the strong potential to strengthen and optimize brain function that is known to be damaged and/or weak. In the improvisational music therapy, the main goal of the therapy with individuals with ASD is to establish, maintain, and develop interaction between the therapist and the client through active music-making processes and to deal with developmental and therapeutic issues that are presented by the client during each stage of therapy process.

Treatment Participants

Music therapy has been used for preschool and school-age children, adolescents, and adults with wide range of different abilities and symptom severity. The most common participants are preschool and school-age children with ASD in music therapy (Geretsegger et al. 2014).

Treatment Procedures

When referral is made to a music therapist, the music therapist assesses the individual’s needs, plans either individual or group music therapy sessions based on the needs of the individual, and implements and evaluates music therapy sessions where appropriate. Following are the typical music therapy procedures:

1. Referral: Referral to music therapy can be made by the parents, doctors, speech therapists, teachers, social workers, etc.

2. Assessment: The music therapist assesses the individual’s needs in terms of his/her strengths and weaknesses through musical responses using various musical activities.
3. Goal setting: Treatment goals and objectives are developed based on the findings of assessment. Therefore, assessment will lead to setting up appropriate treatment plan for individuals with ASD.
4. Treatment implementation: Music therapy sessions can be one-on-one or in a group, which consist of musical activities that are designed to meet the individual’s needs and therapeutic goals.
5. Evaluation: Music therapy sessions are regularly evaluated by the music therapist and often within the interdisciplinary team.
6. Termination of music therapy: The duration of music therapy varies from person to person, depending on the needs of the individual. Short-term therapy typically consists of 10–12 sessions. Long-term therapy can be up to 2 or 3 years. For young children with ASD, music therapy sessions are typically more than 3 months. Children with ASD typically have once, twice, or thrice weekly music therapy sessions for about 20–50 min, depending on attention span and needs of the child. Music therapy is typically offered in an individual (one-to-one), group, and/or family-based (family members such as parents and other siblings) setting.

Kaplan and Steele (2005) investigated 40 music therapy clients with ages ranging from 2 to 49 years with ASD in Cleveland, USA. They found individual music therapy as the most common session type, followed by partner, small group (3–5 subjects), large group (more than 6 subjects), etc.

Efficacy Information

In the last few decades, there have been accumulating research evidences indicating the efficacy and the effectiveness of music therapy for individuals with ASD, with some promising results in

the domains of social, communicative, and behavioral skills (Bieleninik et al. 2017a; Brownell 2002; Buday 1995; Geretsegger et al. 2014; Katagiri 2009; Kern and Aldridge 2006; Kim et al. 2008, 2009). Recently, there have been some systematic or narrative reviews on effects of music therapy for individuals with ASD. It was found that majority of published articles in music therapy for individuals with ASD were case studies with anecdotal evidences, and there have been limited numbers of well-designed empirical investigations typically with small samples (Accordino et al. 2007; Geretsegger et al. 2014; Simpson and Keen 2011). In the recently updated Cochrane meta-analysis of music therapy for ASD, Geretsegger and associates (2014) reported sufficient evidences for music therapy as effective intervention in improving core symptoms of ASD that is in the areas of social communication, social emotional reciprocity, and parent-child relationship. Effect sizes were moderate-to-large. Included ten studies (nine RCTs, 165 children aged between two to nine) of Cochrane review examined short- to medium-term effects of music therapy compared to either standard care (SC) or similar intervention without music. Seven out of ten studies were short-term trials (1–5 weeks) employing a highly structured therapist-directed approach largely using receptive techniques. Remaining three studies were medium-term trials (3–7 months) utilizing a child-centered and interactive approach using improvisation as means of communication between the therapist and the child.

In contrast to the recent Cochrane findings, Bieleninik and associates (2017a) conducted a large-scale, well-designed, multicenter randomized clinical trial (364 children from nine countries) of improvisational music therapy (IMT) for young children with ASD (4–7 years-old), comparing IMT plus standard care (SC) with SC to determine effects of IMT on the core symptoms of ASD. They found no significant difference between IMT and SC on the reduction of core symptoms of ASD. They employed the ADOS (Autism Diagnostic Observation Schedule) social affect domain as primary outcome and SRS (Social Responsiveness Scale) as secondary

outcome measures. The children in their study showed slight reduction of core symptoms over time in both conditions from the ADOS social affect domain. Although there were no significant differences in the primary outcome measure, post hoc exploratory analyses revealed that the children in IMT showed higher proportion of improvement in social communication at 5 months (95/182 [52%]) than the children in SC (76/182 [42%]). They also found significant effects in several SRS subscales. For example, music therapy was found to be more effective at improving social motivation than SC over 5 months.

There could be different levels of explanation and debates on how to understand the contradictory results between the Cochrane review and the most recent RCT as these two types of studies are considered the most rigorous clinical evidence.

Bieleninik et al. (2017b) conducted meta-analysis of 5771 children with ASD aged 7 months to 16.5 years to determine temporal stability of ASD diagnosis and core symptom severity over time. The meta-analysis of their study indicated core symptoms of ASD were markedly stable over time during childhood of these children. Bieleninik and associates (2017b) stated that clinical outcome studies should focus on “other areas, such as quality of life and adaptive functioning.”

In Kaplan and Steele’s investigation (2005) on 40 music therapy clients with ages ranging from 2 to 49 years with ASD, 100% of parents and caregivers of these clients reported that these individuals with ASD generalized skills and responses obtained in music therapy to other environments.

Outcome Measurement

Abovementioned clinical outcome studies used generalized (intervention outcome measured outside of music therapy setting) and nongeneralized (intervention outcome measured within music therapy) outcome measurements to examine effects of music therapy on people with ASD.

Four studies (Bieleninik et al. 2017; Gattino et al. 2011; Kim et al. 2008; Thompson 2012) used standardized and published scales such as

the ADOS/the SRS; the Childhood Autism Rating Scale (CARS); the Early Social Communication Scale (ESCS)/the Pervasive Developmental Disorder Behavior Inventory (PDDBI); and the Vineland Social-Emotional Early Childhood Scales (SEEC)/the SRS.. The ADOS and the CARS are primarily developed as diagnostic tool adapted to intervention studies whereas the ESCS, the PDDBI, the Vineland-EEC, and the SRS are developed and/or used to examine responsiveness to interventions in individuals with ASD. These four studies measured generalized social communication skills utilizing these standardized scales.

However, nongeneralized outcome measurements are still the most common assessments in music therapy, mostly based on either direct or through video recording observations, and/or substantial clinical documentation. For observational outcome measurements, specific target behaviors are defined prior to conducting outcome evaluation. Some music therapy researchers measured specific target behaviors through direct observation using event recordings (Brownell 2002; Kern et al. 2007). Others used video recordings to evaluate behavioral outcomes for children with ASD (Buday 1995; Kern and Aldridge 2006; Kim et al. 2008, 2009).

While it is important to use observational outcome measurements in music therapy, it is also pertinent to develop standardized outcome measurement in music therapy capturing unique benefit of music therapy for the individuals with ASD that is valid, reliable, and comparable to other standardized measurements.

Qualifications of Treatment Providers

Music therapy services are provided by registered music therapists who have completed an accredited music therapy degree program by the music therapy association in their respective country. In the USA, Australia, many countries in Europe, and South Korea, music therapists typically hold either undergraduate or master's degree in music therapy. In the UK, music therapists typically hold a master's degree in music therapy and have state registration with Health Professions Council. In

the USA, there are large numbers of American Music Therapy Association-approved programs providing equivalency or certificate degrees in music therapy for people that have already obtained a degree in related fields. Individuals who have completed an approved music therapy degree program are qualified to take the national board certification examination and can earn the credential of MT-BC (Music Therapist-Board Certified) after passing the exam. South Korea has benchmarked the American system and has set up the national music therapy certification examination for music therapists.

Music-Based Scale for Autism Diagnostics (MUSAD) Assessing Adults with Intellectual Disability

Thomas Bergmann

Berlin Treatment Center for Mental Health in Developmental Disabilities, Ev. Krankenhaus Königin Elisabeth Herzberge, Berlin, Germany

Synonyms

MUSAD

Description

The MUSAD is a standardized observational instrument to assess autistic traits in adults with intellectual disabilities (ID) suspected of having an additional autism spectrum disorder (ASD). The nonverbal and age-independent quality of musical interaction is used as a framework to assess people with speech impairments.

The assessment comprises 11 structured musical-interactive situations to prompt diagnostically relevant behaviors. Detailed step-by-step instructions are given to ensure stability of the application across time and between clients and different raters. First of all, the assessor attempts to engage the client in musical activity,

e.g., joint drumming. In this particular situation, several prompts – tempo change, alternating of hands (right-left stroke), invitation to dialogue by playing a short motif, and a joyful crescendo with a final blow – are set to elicit client reactions in diagnostic relevant behaviors. Secondly, observation priorities are given to recapitulate the assessment with note-taking in free text. In the drumming situation, focus is placed on interpersonal attunement in synchronizing to tempo changes, motor coordination in right-left strokes, nonverbal social reciprocity in back-and-forth playing, and social affect in sharing musical dynamics and intensity. Video recording is recommended to support the assessor in changing roles from being in playful contact with the client to being a distant observer, closely assessing and monitoring client behavior. Thirdly, each of 46 items is coded on a 4-point Likert scale according to ascending symptom severity. Each item is assigned to a situation/prompt (e.g., drumming → “reciprocity in musical interaction”) or even overall (e.g., “eye contact”), and each point is described by quantitative or qualitative behavioral markers. The diagnostic algorithm is formed by 26 items representing the dyadic ASD-construct of social impairments and stereotyped behaviors, including sensory issues, according to DSM-5. A total score is formed by summing up the values of the marked algorithm items. A cutoff point of 30 is proposed to indicate the presence vs. absence of ASD. Especially in borderline cases around 30 points, the diagnostic indication may be discussed, considering ID level, comorbidities including sensory and motor impairments not associated with ASD, or score inconsistencies across domains.

Historical Background

Going far back in the history of ASD, Kanner (1943) described pronounced musical interest and skills in 6 of 11 children in his groundbreaking case series. Up to now, music has played an important role in the therapy and education of children with ASD (Geretsegger et al. 2014, Srinivasan and Bhat 2013). Alongside several

music-based approaches in fostering people with ASD, there have been some semi-structured attempts using the music-therapy setting as a framework to observe and assess autism-related behaviors in children for diagnostic purposes (Oldfield 2006; Wigram 1999).

For decades, the main focus in developing scales and instruments for proper ASD diagnosis was on children and youths, resulting in numerous screening tools and a diagnostic gold standard for this age group. The fact of frequently undiagnosed ASD in adulthood was only recognized relatively recently (Brugha et al. 2011), as was the high prevalence of ASD in the ID population (Saemundsen et al. 2010). Within the low-functioning ASD group, a significantly larger number of comorbid conditions were found as compared with people diagnosed only with ID, demanding individually tailored treatment and support (Cervantes and Matson 2015). However, especially in adults with ID, the symptom overlap of ASD and severe cognitive impairment combined with comorbid conditions represents a major diagnostic challenge. Certain symptoms may be misinterpreted or not recognized, as they may be biased by ► [diagnostic overshadowing](#) and a lack of information about early childhood. This led to the development of various ID-specific ASD screeners that capture an adult ASD-phenotype (e.g., DIBAS-R). Even if the diagnostic gold standard represented by the combination of ► [ADOS](#) and ► [ADI-R](#) is principally applicable in adults with ID, its usefulness is limited owing to reduced feasibility, imbalanced algorithms, and age-inappropriate materials (Sappok et al. 2013). This unsatisfactory situation was the starting point for modifying a semi-structured music-therapy approach for ASD-diagnostic purpose and developing the MUSAD (Bergmann et al. 2009). The concept of assessing interactional skills and stereotyped behaviors in structured but naturalistic situations in direct contact with the client was oriented toward the ADOS. In addition to using a musical-interactional setting to prompt ASD-related behaviors, the MUSAD differs with its concept of increasing demands throughout the entire examination to increase feasibility in

cases of high irritability, along with including motor coordination as a potential ASD marker.

Items were created based on DSM-5 ASD criteria, a review of scales and literature, and clinical experience of the test developers in the field of the targeted population and music-based interventions. The framework for developing the MUSAD was a specialized treatment center with both in- and outpatient clinics, for adults with ID and mental health problems.

A guideline-compliant diagnostic work-up has been established on the basis of an expert consensus conference supported by various ASD measures (Bergmann et al. 2016). This allowed the evaluation and validation of the MUSAD assessment based on consecutive samples and an external criterion for diagnostic classification reflecting clinical reality. The future direction will be to develop a brief version of the instrument (MUSAD-Short) aiming to improve economy and user-friendliness and allowing ASD screening in people with ID including children and adolescents.

Psychometric Data

Psychometric properties of the MUSAD have been evaluated in a pilot study assessing feasibility, user-friendliness, and construct validity ($N = 80$; Bergmann et al. 2015a, b) and a validation study focusing mainly on inter-rater reliability and criterion validity ($N = 124$; Bergmann et al. 2019).

Feasibility was 95% ($N = 80$). Compared with the play-based ADOS applied in parallel, the MUSAD showed considerably lower dropout rates (5% vs. 15%) in $n = 40$ cases. Practicability of the test draft was supported by the successful video-based coding of one case by 12 raters from different professional backgrounds who were unfamiliar with the instrument. Plausibility of the items and coding descriptions were judged as good by questionnaire, even if the substantial coding effort was criticized.

A confirmatory factor analysis supported a three-dimensional construct ($F1 =$ social interaction, $F2 =$ stereotyped behaviors including sensory issues, $F3 =$ motor coordination). Testing

the MUSAD construct fit indices indicated a good model fit ($CFI = 0.97$, $RMSEA = 0.06$, 90% CI [0.05–0.07] and $WRMR = 1.02$), even if the chi-squared test of exact model fit suggested significance (χ^2 ($df = 626$) = 822.8, $p < 0.001$).

Concurrent validity was supported by substantial and significant correlation with the convergent ASD screener DiBAS-R ($r(111) = 0.62$, $p < 0.001$) and a negligible nonsignificant correlation with the discriminant aggression scale MOAS ($r(56) = 0.15$, $p = 0.252$). Scale reliability was high ($\alpha = 0.95$).

Inter-rater agreement based on the sum scores across 4 raters in $n = 22$ cases was excellent ($ICC = 0.92$). Test-retest reliability in $n = 9$ ad hoc test repetitions was moderate ($ICC = 0.73$).

Criterion validity was calculated by applying an ROC analysis. With a cutoff score of 30 points, 76.6% of all individuals assessed were classified correctly ($\kappa = 0.52$; sensitivity = 0.79, 95% CI [0.68–0.87] and specificity = 0.74, 95% CI [0.59–0.85]. The positive predictive value was 0.82, 95% CI [0.74–0.88], and the negative predictive value was 0.69, 95% CI [0.59–0.78]. The AUC values were 0.81, 95% CI [0.73–0.88] for the overall score, 0.79, 95% CI [0.71–0.88] for the social interaction score, and 0.78, 95% CI [0.70–0.87] for stereotyped behaviors including sensory and motor issues.

Clinical Uses

The MUSAD is used clinically as one part in a multidimensional team-based diagnostic work-up as proposed by current guidelines (NICE 2012). The targeted population is adults (age >18 years) with ID and impaired speech. The implementation requires approximately 90 min, including video-based coding. Because of this relatively high effort, comparable to the ADOS and ADI-R, it might be useful to apply the MUSAD in a two-stage diagnostic work-up after ASD screening in case of diagnostic uncertainty. The assessment can be performed by a music therapist or other professionals (psychologists, pedagogues) with basic musical skills. For all users a specialized training is required. This includes correct implementation as well as behavioral observation and

coding supporting inter-rater agreement. A special feature of the MUSAD is the inclusion of motor coordination, considered a cardinal feature of ASD throughout the entire spectrum (Fournier et al. 2010). This may support differential diagnostic discrimination, e.g., over against psychosis or trauma-related disorders/hospitalization. As with other ASD scales, the MUSAD should not be used as a stand-alone instrument for diagnostic classification, but it may be a useful resource in team-based diagnostic procedures.

Definition

“Emotion elicited through musical stimuli, including subjective, cognitive, and physiological responses”.

Historical Background

Considerable research and study has been dedicated to understanding emotional processing in autism spectrum disorder (ASD). Differences in emotion recognition and emotional responsiveness are commonly noted in clinical presentations (Begeer et al. 2008). As a result, considerable attention has also been dedicated to better understand emotional processing in the research literature. Historically, these investigations focused on social stimuli such as viewing emotional faces. Results from multiple meta-analyses indicate that, despite considerable heterogeneity, overall impairments in facial emotion recognition exist and cannot be completely accounted for by intellectual ability of people with ASD (Lozier et al. 2014; Uljarevic and Hamilton 2013). These differences seem to be related, at least in part, to different ways of processing faces such as reduced eye fixation (Jones et al. 2008; Klin et al. 2002; Pelphrey et al. 2002) and appear to be strongest for the emotions of *anger* and *fear* (Lozier et al. 2014). The question then arises if these patterns are present for other emotional material, such as music.

There is a long history of people with ASD showing an interest in music. Pioneering work by Heaton and colleagues highlighted strengths in musical processing of ASD children compared to children without ASD. Their work and that from other labs have shown musical strengths including memory of musical information and pitch perception (e.g., discrimination, detection, and memory) (see Quintin (2019) for a review). Additionally, the experience of music may be largely similar for people with ASD with evidence showing similar levels of interest in, time spent listening to, and reasons for listening to music as the typical listener (Allen et al. 2009; Bhatara et al. 2013).

Music has a powerful influence on emotional states of humans, and there is a wealth of information highlighting how music can activate neural pathways similar to other nonmusical forms of emotional stimuli and people are consistently able to identify specific emotions depicted through music (see Koelsch (2014) for a review; Schaefer 2017). The actual musical elements that tend to

elicit a particular emotion is varied and complex; they include pitch variation, rhythm, tempo, tonality, timbre, articulation, musical mode, harmony, and melodic direction and motion, to name a few (Gabrielsson and Lindström 2011). The scientific interest in music-evoked emotion and ASD has direct applications, most notably with regards to the use of music therapy. Music therapy, or complementing traditional therapy with music, is a promising avenue for improving outcomes (see reviews by Geretsegger et al. 2014; James et al. 2015) including verbal (Chenausky et al. 2016), general communication (Sharda et al. 2018), and social skills of children with ASD such as social-emotional reciprocity, quality of social interactions, and initiation of social exchanges (LaGasse 2017).

Current Knowledge

Identification of Music-Evoked Emotion

There have been several studies that have directly investigated the question of “can people with ASD identify emotions in instrumental music as well as their peers without ASD?” Thus far, the evidence suggests that the answer to that question is likely “yes.” There are studies that have clearly showed intact identification of specific emotions in music including *happy*, *sad* (Heaton et al. 1999; Whipple et al. 2015), *fear* (Quintin et al. 2011; Stephenson et al. 2016), *disgust*, and *anger* (Whipple et al. 2015). Other studies give evidence for intact ability to match emotional social scenes with corresponding musical excerpts (Heaton et al. 2008) and assigning emotional valence (i.e., positive vs. negative) to *happy* and *sad* music (Gebauer et al. 2014). One study found that children and adolescents with ASD did not differ in their emotional labeling skills, but this was the case only after statistically controlling for differences in verbal intellectual ability (Quintin et al. 2011). Another study found possible age-related differences between youth with and without ASD, specifically for *scary* music, in that younger autistic children tended to be slightly more accurate in identifying *scary* music compared to their older autistic peers, the opposite

age-related pattern was found for children and adolescents without autism (Stephenson et al. 2016). Thus, emotion identification of people with ASD appears to be largely intact, although there may be nuanced effects of age and verbal ability that will need to be explored and clarified with future research.

Response to Music-Evoked Emotion

In addition to the behavioral aspect of recognizing emotional characteristics of music, there is also the psychological and physiological responsiveness to music-evoked emotion. Parents of children with ASD rate their children’s emotional responsiveness to music similarly to those of their non-ASD peers (Bhatara et al. 2013) and children themselves do not differ in their self-reported perception of intensity of music-evoked emotion in laboratory-based studies using simple rating scales (Quintin et al. 2011; Stephenson et al. 2016), with similar results appearing for adults (Caria et al. 2011). However, according to studies with autistic adults, they tend to describe emotional reactions to music using different words than non-autistic adults, which may be related to difficulties understanding one’s internal emotion states and struggling to put words to emotional experiences, often referred to as alexithymia, (Allen et al. 2013; Allen et al. 2009), which is often associated with ASD (Bird and Cook 2013; Poquérousse et al. 2018). Given the intact ability of autistic people to recognize and match emotional music to expressed emotions, music has potential to be used as a tool in developing emotional understanding and expression outside of music for people with ASD (Allen and Heaton 2010).

Evidence on physiological responsiveness to music is just emerging. Adults with ASD showed no difference in their galvanic skin response compared to non-autistic adults (Allen et al. 2013), whereas autistic children and adolescents had reduced physiological response compared to their neurotypical peers in another study when listening to the same instrumental music stimuli (Stephenson et al. 2016). Neuroimaging studies have shown that brain networks typically involved in the processing of music-evoked emotion, including reward circuitry, are intact for

people with ASD, at least for *happy* and *sad* music (Caria et al. 2011; Gebauer et al. 2014). Although some results indicate that listening to *happy* music evoked somewhat *reduced* activation in certain areas including insula (Caria et al. 2011), other results show *increased* activation for *happy* vs. *sad* music in insula as well as dorsolateral prefrontal cortex, possibly related to increased arousal and cognitive processing (Gebauer et al. 2014). Notably, current neuroimaging studies have focused exclusively on autistic adults and a fairly narrow range of music-evoked emotions (i.e., *happy* and *sad*). Investigating a wider range of emotions is needed, especially given the propensity towards anxiety and fear in autistic individuals including differences in sensory and cognitive processing of fear (South and Rodgers 2017).

Despite heterogeneity in research findings within ASD samples, which is not uncommon, the growing literature paints a picture of overall intact psychological and physiological responsiveness to music-evoked emotion. However, similar to results from emotion identification, there may exist nuanced differences in emotional experience, particularly when different emotions are considered.

Future Directions

Despite the current knowledge of the processing of music-evoked emotion of people with ASD, there are still many unanswered questions. Additional research is needed using a wider range of emotions, especially in neurophysiological studies. In particular, research is needed regarding response to *anger* and *fear*, which are important for both emotional processing and emotional regulation of people with ASD. Another potential avenue of further research is variations in musical stimuli used in studies. The majority of studies have relied on existing music from classic repertoire and film, with only a few selections crafted specifically for research use (Whipple et al. 2015). Additionally, the use of lyrics in emotional music is also understudied as well as the impact of pairing emotional music to other social-emotional

contexts such as movies. Many studies show relatively high levels of accuracy in emotion identification among participants possibly suggesting that the completion of the tasks is too easy. Finding ways to increase the difficulty of musical tasks may provide more variability from which group differences may arise. Only one study has investigated music-evoked emotions using stimuli which vary in level of emotional intensity (Bhatara et al. 2010). Bhatara et al. found that participants with ASD did not provide ratings with as much variability as those without ASD, but the participants with ASD also had lower verbal intellectual ability than those in the comparison group. Additional work varying level of intensity or study designs using congruent vs. incongruent emotional information (e.g., *happy* music with *angry* lyrics) may be possible ways to achieve different levels of difficulty to increase the variability within emotional identification accuracy.

The vast majority of research investigations up to this point have included people with intact intellectual ability. Similar to other areas of research, music-evoked emotion studies need to include people at all levels of the autism spectrum in order to understand the musical experience among those with minimal verbal ability. Preliminary results indicate that children and adolescents with ASD with verbal and cognitive skills ranging from the lower to higher ranges can accurately recognize music-evoked emotions (Dahary et al. 2018). Additionally, relatively little is known about the developmental trajectory of musical experience and ASD, although some research points to possible age-related differences (Stephenson et al. 2016). Longitudinal studies investigating music-evoked emotion at all points of development, from early childhood into older adulthood, would shed valuable light into this area. With a better understanding of the differences and similarities of processing of and responses to music-evoked emotion, we may have access to additional tools for the diagnosis and treatment of autism. One music-based autism diagnostic assessment tool for adults with developmental disabilities has already been developed (Bergmann et al. 2015), and there is potential for other applications of music therapy including

development of executive functioning skills in young children (Frischen et al. 2019). Furthermore, with improving technology of wearable physiological measurement devices, neural imagining, and behavioral strategies, the prospect of including a wide range of individuals is better than ever.

Many of these promising avenues are already being pursued (Dahary et al. 2018; Sivathanan et al. 2019), although there is room for more research to be done in this area. As with much autism-related research, studies of music-evoked emotion and ASD is lacking in larger, high statistical power studies. Multisite collaborations can help with this as well as researchers considering including musical stimuli and paradigms in larger clinical trials and lab-based research of emotion processing.

In sum, people with autism display generally intact accuracy and processing of music-evoked emotion. The use of music-evoked emotion has great potential for scientific and clinical benefit in autism spectrum disorder and remains a promising field for future endeavors.

Sciences, UC Davis M.I.N.D. Institute,
Sacramento, CA, USA

Synonyms

Eye contact; Eye-to-eye gaze; Social gaze; Visual attention to eyes; Visual orienting to eyes

Definition

What Is It?

Mutual gaze occurs when two people make eye contact or look into each other's eyes. Mutual

gaze is an important part of social communication and perception of others' emotion states and is the one of the foundational skills necessary in the development of joint attention (George and Conty 2008; Morales et al. 2005; Saito et al. 2010; Senju and Johnson 2009). Mutual gaze has been described as "the most powerful mode of establishing a communicative link between humans" (Farroni et al. 2002).

When Does It Occur?

From birth, infants are innately motivated to gaze into their caregivers' eyes. In fact, the field of vision of newborns is approximately the distance required to make eye contact when held by an adult (Stern et al. 1985). Infants prefer to look at faces over other stimuli, especially faces that engage them in mutual gaze (Farroni et al. 2002). Eye-tracking studies have revealed that when looking at faces, even infants preferentially fixate on the eyes over other facial features (Mauer and Salapatek 1976).

Mutual Gaze and ASD

One of the most prominent features of autism spectrum disorder (ASD) is an atypical pattern of eye contact and reduced levels of mutual gaze with social partners (Klienmann et al. 2010). Although reduced levels of gaze behavior at 6 months was not found to be predictive of autism diagnosis at 24 months (Young et al. 2009), toddlers with autism do show abnormal gaze to the eye region and decreased shared affect (Chawarska et al. 2010). Eye-tracking data for children with ASD have shown active avoidance of direct eye contact through increased gaze shifts away from the eye area (Klienmann et al. 2010). The DSM-IV-TR includes reduced eye contact as one of the symptoms of ASD: "marked impairment in the use of multiple nonverbal behaviors (e.g. eye-to-eye gaze, . . .) to regulate social interaction and communication" (American Psychiatric Association 2000, p. 70).

There are currently four models that are used to explain the decreased levels of mutual gaze or eye contact in children with ASD:

1. *The affective hyperarousal model* which posits that gaze avoidance is an adaptive response for individuals with ASD who find focusing on the face and eyes of others to be strongly aversive
2. *The affective hypoarousal model* which posits that individuals with ASD experience hypoactivation of the amygdala, which interferes in the association of a positive social reward with making eye contact, resulting in reduced levels of eye contact
3. *The communicative intention detector model* that proposes that individuals with ASD engage in less eye contact because they do not understand the social salience of eye contact in understanding others' states
4. *The fast-track modulator model* which states that atypical eye contact in ASD could be caused either by an impairment in the subcortical face and eye contacting detecting route or in the network of cortical and subcortical structures specializing in the processing of social information (Senju et al. 2009)

Mutual Regulation

Amanda C. Gulsrud

UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, USA

Synonyms

Co-regulation; Emotion regulation; Emotional synchrony; Self-regulation

Definition

The construct of emotion regulation refers to “the extrinsic and intrinsic processes responsible for monitoring, evaluating and modifying emotional reactions” (Thompson 1994). Important to this definition is the emphasis on both intrinsic and extrinsic processes, which may include both internal or self-driven processes and external or mother-driven support. This mother-driven support of the child's emerging emotional processes is co-regulation.

The development of emotion regulation is a process that occurs over the first years of life. Beginning in infancy, children learn to regulate emotions, attention, and behaviors through the external scaffold of mothers. The process gradually becomes an internal, self-driven process (Kopp 1989). As children gain a greater ability to regulate these processes, they also show a greater ability to remain flexible while facing the ongoing social demands of their environment.

Mother-child interaction research has contributed to our knowledge of emotion co-regulation by emphasizing the dynamic and interpersonal nature of the construct. These studies have found that typical mothers and children are sensitive to each other's emotional states and that mothers regulate child emotional states by reading emotion signals and modulating child arousal (Field 1994). In addition, work in this area has found that the quality of interpersonal regulation between

mother and child predicts later social-emotional outcomes in the child, including self-control and social competence (Feldman et al. 1999).

Several studies have begun to examine the development of emotion regulation in children with autism. Bieberich and Morgan (2004) employed parent report measures to examine emotion regulation outcomes. In another study, emotion regulation and temperament in children with autism spectrum disorder was measured by behavioral coding of maladaptive and adaptive regulation strategies during a mildly frustrating delay task. Results showed that children with autism employed less adaptive strategies and a greater range of strategies compared to typical controls (Konstantareas and Stewart 2006). These findings are among the first empirical support for a specific disturbance in emotion self-regulation in children with autism.

A recent study explored the development of emotion co-regulation in young children with autism and their mothers within the context of an early social-communication intervention (Gulsrud et al. 2010). Results showed that children displayed significant distress in almost half of their interactions with their mothers, and these episodes of distress lasted on average 20% of the total length of the interaction. Children most frequently engaged in active strategies (tension release, avoidance, and distraction). Similarly, mothers most frequently engaged in active strategies (redirection of attention, prompting/helping, and physical strategies) during child negativity. These results suggest that both mothers and children are actively working together to regulate the child's emotions and that co-regulation is a viable construct for study in this population.

Mutually Acceptable Written Agreement (MAWA)

Lindsey Capece

Quinnipiac University, Hamden, CT, USA

Definition

A “mutually acceptable written agreement” is a binding document that is the result of a mediation session. Mediation is a negotiation session, typically used as an informal alternative to the adversary system, facilitated by a neutral third party who tries to help the parties in the dispute to reach a mutually acceptable written agreement.

The agreement can cover a wide range of issues including issues that would not be recognized in a court of law. There is some uncertainty as to whether a mutually acceptable written agreement is legally enforceable. Most states require that these agreements be reduced to writing and be signed by both parties, and many states require that the agreement be filed in court. Furthermore, there are often statutes that provide requirements for an agreement reached in a particular type of mediation setting. In the absence of legislation, one must look to common law contract principles as authority on whether the agreement is enforceable. These agreements may also be subject to agency law for the purpose of determining whether those entering into the agreement have the authority to do so.

Naltrexone

Evdokia Anagnostou¹ and Deepali Mankad²

¹Department of Pediatrics, University of Toronto, Clinician Scientist, Bloorview Research Institute, Toronto, ON, Canada

²Holland Bloorview Kids Rehabilitation Hospital, Bloorview Research Institute, Toronto, ON, Canada

Synonyms

Depade; Naltrexone hydrochloride; Revia

Indications

Alcohol dependence

Mechanisms of Action

Naltrexone is an opiate antagonist with minimal agonist activity.

Clinical Use (Including Side Effects)

Naltrexone is not currently approved for the treatment of ASD-related symptoms but enjoys some off-label use.

A series of early open-label studies had suggested significant improvements in self-injurious behaviors (SIB). The side effect profile was relatively benign.

Following early data, there have been a few small controlled studies (max sample size 41, Campbell et al. 1993) treating children between the ages of 2.8 and 19 years with naltrexone. A nice systematic review by Elchaar et al. in 2006 has summarized available data in ASD. Overall, the data does not support the use of naltrexone for the treatment of core symptom domains of ASD, despite original hypothesis regarding abnormalities in the endogenous opioid system in ASD (Panksepp 1979). However, preliminary data suggests that at least a subgroup of children with ASD may show improvements in self-injurious behaviors with naltrexone. Still there is no clarity regarding the dose (doses used vary from 0.5 mg/kg weekly to 2.35 mg/kg single dose) and/or duration of treatment. There is also lack of clarity about whether higher doses are more or less effective, with some studies suggesting that doses of 2 mg/kg/day or higher may have less selectivity for the opiate receptor, therefore competing with the opiate antagonism effect.

The most commonly reported side effect in ASD studies is sedation. The bitter taste of naltrexone may interfere with compliance. Naltrexone carries an FDA black box warning regarding hepatic insufficiency, but no elevation in liver enzymes has been reported so far in patients

with ASD. Gastrointestinal upset and two cases of panic attacks have also been reported.

At this point, it is hard to make a recommendation regarding naltrexone. If it were to be used, a reasonable dose range is between 0.5 and 2 mg/kg/day. Safety needs to be monitored, especially regarding the FDA black box warning. A large randomized controlled trial of naltrexone targeting SIB and exploring predictors of response is likely warranted.

Definition

A narrative assessment is the analysis of a story told by an individual to assess language and communication. A narrative can be used to measure pragmatic language use because it involves recounting a personal experience or retelling a story to another individual. Narratives can be examined for their structure (e.g., sentence complexity, story components), content (e.g., use of mental state terms), and/or style of presentation (e.g., use of prosody, gestures, facial expressions).

Narrative Language in ASD

Michelle Lee^{1,2} and Molly Losh³

¹NYU School of Medicine, New York, NY, USA

²Department of Communication Sciences and Disorders, Northwestern University, Evanston, IL, USA

³The Roxelyn and Richard Pepper Department of Communication Sciences and Disorders, Northwestern University, Evanston, IL, USA

Definition

Narrative (i.e., storytelling) is a ubiquitous form of communication and primary means of sharing experiences with others. Organizing experiences

through narrative imposes temporal and causal order to events, providing meaning and interpersonal significance to experiences. Narrative is the primary means of sharing one's world of experience with others and plays a major role in forging interpersonal connections. In autism spectrum disorder (ASD), narrative abilities are impaired, particularly in open-ended conversational contexts that pervade daily interactions. Given the centrality of narrative to social interactions, characterizing the narrative profile in ASD is critical to understanding the origins of this group's difficulties with more complex social language use and intervention development.

The development of narrative competence draws on a number of linguistic, cognitive, and social cognitive skills that are impacted in ASD. Observed narrative impairment in ASD has been linked to deficits in structural language and social cognition (e.g., failure to identify the needs of one's listener) and may also be associated with executive function deficits (e.g., difficulties with attention, inhibition, and working memory) and a weak central coherence cognitive style (e.g., a focus on irrelevant details at the expense of the whole). Difficulties across these domains likely can impact both microstructural (e.g., length, complexity of word use, grammatical markers) and macrostructural (e.g., overall form and content) elements of narrative. For instance, impairments in structural language may result in reduced grammatical complexity, limiting one's ability to communicate temporality of events and to establish causal relationships between events. Further, social cognition is important for recognizing the emotional experiences of those involved in the story and adapting narrative style and content based on listener responses.

Although narrative abilities vary within individuals with ASD, particularly as a function of comorbid cognitive and language impairment, studies suggest a pattern of relative strengths in highly structured contexts (e.g., wordless picture books) and weaknesses in more open-ended conversational contexts that are typical of daily interactions. Generally, in more structured narrative tasks, individuals with ASD produce narratives

of similar length, with comparable rates of grammatical markers, emotion-state words, and basic narrative elements (e.g., main characters or setting) as those of typically developing peers. However, individuals with ASD demonstrate relative challenges in many aspects of narrative, with the most consistent difficulties observed in the use of evaluative devices, or statements that infuse psychological perspective within a narrative, such as a causal explanation of a character's emotion. Narratives of individuals with ASD have also been characterized by greater frequency of off-topic remarks, overly formal language, and reduced overall coherence. These difficulties have been observed across the lifespan of individuals with ASD, although research has primarily focused on childhood and early adolescence.

Given that difficulties with narration are most prominent in conversational contexts, it will be critical for future research to focus on the assessment of this form of narrative in order to elucidate difficulties most relevant to daily interactions. Similarly, a targeted intervention approach that focuses on developing conversational narratives has the potential to improve the social and communicative experiences of individuals with ASD.

National Guideline for the Assessment and Diagnosis of Autism Spectrum Disorders in Australia

Giacomo Vivanti¹ and Andrew Whitehouse^{2,3}

¹A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, USA

²Telethon Kids Institute, University of Western Australia, Nedlands, WA, Australia

³Research Section (Psychology), University of Western Australia, Crawley, WA, Australia

Definition

The Australian National Guideline for the Assessment and Diagnosis of Autism Spectrum Disorders is a clinical Guideline comprising 70 recommendations designed to “create greater consistency in diagnostic practices across the country to ensure individuals on the autism spectrum and their families can receive the optimal clinical care.”

Historical Background

Australia is a high-income country with a population of approximately 25 million people spread over a geographical area around the same size as the USA or continental Europe. The prevalence of ASD in Australia is estimated between 1 and 2.5% (Randall et al. 2016).

The Australian system of government includes a central federal government and six states which,

together with two self-governing territories, have their own constitutions, parliaments, governments, law, as well as systems for health, education, and community services, including those impacting individuals with disability and autism spectrum disorder (ASD). Local government is the third tier of government in Australia, with each city or municipal area providing services for individuals with disability, including those with ASD.

As previous report commissioned by the Cooperative Research Centre for Living with Autism (Autism CRC) and the Commonwealth Department of Social Services, variability between states and territories in diagnostic practices and standards complicates the provision of ASD diagnosis in Australia (Taylor et al. 2016). For example, some states require diagnostic evaluations to be conducted by multi-disciplinary teams, while in other states, diagnostic decisions can be made by a sole clinician. Disparity in resources and in the availability of trained clinicians between urban and rural or remote areas was highlighted as a further challenge. An additional source of fragmentation is the difference in diagnostic standards between the health, education, and disability public services at the state and federal level, resulting in the risk that diagnostic decisions provided by one service (e.g., health system) would not be recognized by another system (e.g., the school system). As highlighted in the report, uneven diagnostic standards involve the risk of unequal service provision.

Current Knowledge

In response to the challenges highlighted in the 2014 report, the National Disability Insurance Agency (an agency of the Australian federal government) sponsored the creation of the first Australian National Guideline for the Assessment and Diagnosis of Autism Spectrum Disorders, which was developed by the Autism CRC with the stated purpose to “create greater consistency in diagnostic practices across the country to ensure individuals on the autism spectrum and their

families can receive the optimal clinical care.” The specific objectives were to develop a guideline that:

1. Describes a rigorous framework for accurately determining whether an individual meets diagnostic criteria for ASD
2. Outlines a comprehensive approach to identify related support needs
3. Contains sufficient flexibility to apply to the assessment of a child, adolescent, or adult of any age, gender, cultural or language background, communication or intellectual capacity, and medical complexity, living anywhere in Australia
4. Describes a feasible process for clinical service providers to administer across the full breadth of community settings in Australia, including public and private healthcare settings
5. Meets the needs and expectations of individuals being assessed and their caregivers

Published in 2018, the guideline content was developed by an expert committee chaired by Andrew Whitehouse (Whitehouse et al. 2018). The expert committee was responsible for conducting a detailed research process that collected and collated new and existing scientific, clinical, and consumer knowledge and generating clinical recommendation that would best apply to the local context.

The guideline is notable for the extensive consultation with a range of stakeholders, including family advocates and self-advocates, and the extensive research to assess the evidence. The development process included a steering committee, which comprised members of the national peak bodies of professions commonly involved in the diagnosis and management of individuals on the autism spectrum, as well as members of service providers and advocacy groups (including adults with a diagnosis of autism). Face-to-face consultation workshops were also held in each state of Australia, as well as a “virtual” workshop held via videoconference that focused on issues for rural consumers. An open feedback process also allowed any individual in Australia to comment on a draft version of the guideline.

The guideline was developed in accordance with six guiding principles:

1. Evidence based: Clinical diagnosis is most effective and safe when it is based on rigorous scientific evidence.
2. Individual and family centered: The primary sources of information required during an assessment of ASD concerns are the individual undergoing assessment and their family members (most notably, caregivers and support people).
3. Holistic framework: An individual is far more than the autistic behaviors, and an exclusive focus on the evaluation of ASD behaviors during the diagnostic process will fail to provide an adequate clinical appraisal of the individual.
4. Strengths focused: The strengths of an individual and their family are as important for service delivery as identifying their challenges.
5. Equity: All individuals, regardless of age, gender, cultural background, socioeconomic status, or geographical location, must be able to access a timely and rigorous assessment.
6. Lifespan perspective: People continue to grow and change throughout their lives as they are faced with new tasks, challenges, and opportunities, and consideration in clinical decision-making of the lifetime of a client is critical to providing optimal clinical care.

There are several key features of the guideline. First, the guideline is notable for the adoption of a person-centered approach, including the indication that the child's profile of strengths and needs, rather than the diagnostic status alone, should be used to make decisions on treatment and services.

Second, the guideline adopts a multistage approach to diagnosis. This includes a comprehensive needs assessment (including an assessment of functioning and medical evaluation), followed by a diagnostic evaluation by a single clinician and the involvement of a larger diagnostic team for more complex cases.

Third, the guideline provides recommendations around how, where, and when each stage of the diagnostic process should occur and also the competencies for professionals involved in the diagnostic process.

Finally, the guideline provides a detailed summary of the latest scientific and clinical knowledge about how the behaviors used to diagnose autism can vary according to certain factors. These factors include age, intellectual and/or communication capacity, sex and/or gender, culturally and linguistically diverse backgrounds, and other complex psychosocial factors.

Each of the 70 clinical recommendations is linked to an individual table that describes the evidence underpinning a given recommendation from various scientific, clinical, or community sources.

In July 2018, the guideline was endorsed by the peak organization in Australia for health evidence, the National Health and Medical Research Council, as representing optimal clinical care.

Future Directions

The Australian government will release a nationwide implementation plan for the guideline in the second half of 2019. The guideline is to be updated every 5 years, with the next update scheduled in 2023.

Division, White Plains, NY, USA

²UCLA, Los Angeles, CA, USA

Major Areas or Mission Statement

The National Research Council (NRC) is part of the National Academy of Sciences in the United States. It is a private, nonprofit society of distinguished scholars engaged in scientific research, mandated by Congress to advise the US federal government on scientific matters. The relevance to autism is that the NRC published a report in 2001 integrating scientific evidence concerning the effects and features of early intervention programs for children with autism. This report was written by an interdisciplinary committee of experts from education, psychology, psychiatry, neurology, speech-language pathology, and augmentative communication convened by the NRC for several years specifically for this project. The charge to the committee was to review the scholarly literature, including research, theory, and policies, to create a framework for evaluating the scientific evidence concerning educational interventions for children under age 8 who have autism. The charge also included specific suggestions to consider the role of early intervention, diagnosis and classification, inclusion, assistive technology, and the rights of children with autism within the United States (Individuals with Disabilities Education Act).

Landmark Contributions

The NRC report is similar to clinical guidelines provided by organizations in other countries (such as by the National Health Service in the United Kingdom) and from particular groups within the United States (e.g., National Autism Standards project; Wilczynski et al. 2009; American

Academy of Neurology; Filipek et al. 2000) but differed from some other reports in that the NRC committee members were well-known scholars from a range of disciplines and theoretical perspectives appointed by a panel of eminent scientists at the Academy, as opposed to members of a specific professional organization (e.g., American Academy of Pediatrics 2007) or a particular bureaucratic entity (e.g., National Health Service or New York Board of Health; New York State Department of Health Early Intervention Program 2005) or a self-nominated group (National Autism Standards; Wilczynski et al. 2009). The committee agreed on standards with which they would evaluate research. Public meetings were held in which researchers and agencies presented information; much of this information is summarized in a series of papers published in the *Journal of Autism and Developmental Disorders* in 2002 (Baranek 2002; Goldstein 2002; Horner et al. 2002; Kasari 2002; Mandlawitz 2002; McConnell 2002; Turnbull et al. 2002; Wolery and Garfinkle 2002). The committee achieved consensus for a number of recommendations which helped to shape educational services for young children with autism in the United States. The NRC report has been used by school systems and state agencies as well as the federal government and families as a guideline for scientifically based approaches to diagnosis, education, treatment, and policies.

Major recommendations include (see National Research Council [NRC] 2001):

1. Children with any autism spectrum disorder (autism, Asperger syndrome, atypical autism, PDD-NOS, childhood disintegrative disorder, Rett syndrome), regardless of level of severity or function, should be eligible for special education services within the category of autism, as appropriate to the child's needs.
2. Early identification and screening for autism, as is done for vision and hearing, should be promoted through research and training of first-line professionals.
3. Children should receive multidisciplinary assessments as soon as possible after identification. Follow-up assessments 1–2 years after the initial evaluation should be considered

- standard because of the many changes that occur during preschool years in autism.
4. Educational approaches to autism must include provision of information to families as well as ongoing consultation and individualized problem-solving and an opportunity to learn techniques for teaching their children new skills and reducing difficult behaviors. Families' concerns and perspectives should help shape educational planning.
 5. Ongoing measurement of treatment objectives and progress must be documented frequently and interventions adjusted accordingly. Objectives should be accomplished within a year, and interventions or objectives should be changed if there is little progress in 3 months. Objectives should be behaviors that are anticipated to affect a child's participation in education, the community, and/or the family and include generalization across environments.
 6. Educational services should begin as soon as a child is suspected to have an autism spectrum disorder. Services should include a minimum of 25 h a week, 12 months a year in which a child is engaged in systematically planned, developmentally appropriate educational activities directed toward identified objectives. What constitutes these hours and how structured the interventions are may vary dramatically depending on the child's age and abilities, the priorities, and supports available to a family within a community but should be specified individually for each child.
 7. Priorities of focus are functional spontaneous communication, social instruction delivered throughout the day in various settings, cognitive development, play, and academics (when appropriate). As much as is appropriate for an individual child, specialized instruction should take place in a setting in which ongoing positive social interactions can occur with typically developing children.
 8. Coordinated, systematic strategies should be developed to fund interventions in local communities and schools so that the cost is not borne by parents, caregivers, or local school systems and so that there is continuity of care.
 9. A federal joint agency task force should be created to address policy issues related to autism spectrum disorders (see US Interagency Autism Coordinating Council; <http://iacc.hhs.gov/>). It was recommended to the Office of Special Education Programs that personnel preparation programs for teaching of children with autism be accelerated.
 10. Standards for adequate description and design for intervention studies were recommended in order to allow more useful interpretation of results, particularly given the range of skills of children with autism. A call was made for stricter requirements to tie measures of efficacy to program development in autism.
 11. Comparisons of different interventions were prioritized as well as the development of research designs that identify the "active ingredients" of interventions and that consider interactions between child and family variables and the effectiveness of different approaches.

Major Activities

The NRC Committee on the Effectiveness of Early Intervention was a committee convened only for this specific project and so is no longer in effect. The National Research Council, along with the Institute of Medicine and National Academy of Engineering, continues to provide reports and makes recommendations as charged by the National Academy of Science and the US federal government on other issues.

Natural Environment

Andrea McDuffie

MIND Institute University of California-Davis,
Sacramento, CA, USA

Definition

Natural Environment Intervention (NEI) or Natural Environment Training (NET) is a language intervention approach for children with autism that was developed by Sundberg and Partington (1999) based upon Skinner's Analysis of Verbal Behavior (1957). NET represents an extension of ABA and discrete trial training approaches. In a manner similar to Pivotal Response Training and Milieu Language Teaching, NET emphasizes the use of intrinsically motivating materials, focuses on the child's immediate interests (following the child's lead), and teaches in the child's everyday environment. This type of approach addresses child motivation and generalization issues by using materials that are reinforcing for the child and teaching within the same contexts that skills will be used. In addition, by making available materials that are reinforcing to the child, NET focuses on allowing the child to initiate teaching episodes to improve manding (requesting) and to increase the initiation of spontaneous communication attempts.

Natural Language Paradigm

Lisa Shull

Division of Neurodevelopmental and Behavioral
Pediatrics, Golisano Children's Hospital,
University of Rochester School of Medicine,
Jamaica, NY, USA
Clinical Psychology, Long Island University,
Brooklyn, NY, USA

Definition

The Natural Language Paradigm (Koegel et al. 1987) is a teaching approach targeting verbal language acquisition for children with severe language deficits associated with autism. Compared to more structured behavioral treatments (e.g. discrete trial teaching), this loosely structured intervention aims to create a learning environment for the child that more closely resembles a natural language speaking situation and apply teaching approaches based on operant conditioning in that environment. This combination is intended to increase and generalize the child's use of communicative speech across settings.

Historical Background

NLP has its origins in work on incidental teaching conducted in the 1960s (e.g., Hart and Risley 1968, 1974). In the 1980s, Risley and McGee (McGee et al. 1983, 1985) began studying ways to adapt incidental teaching for children with autism. Combining this work and research by Koegel, Schreibman, and others on the unique learning styles of these children (e.g., a tendency to focus on only one component of a complex stimulus), Koegel and colleagues developed the Natural Language Paradigm. They presented it as an alternative to more structured operant teaching procedures (e.g. Hewett 1965; Lovaas 1966, 1977). Although there was evidence that these structured procedures were effective in teaching vocabulary and other language skills, many argued that they did not demonstrate sufficient generalized improvement

in functional speech. In an effort to address this inadequacy, researchers started to explore other ways to teach communication, such as sign language and symbol language. This shortcoming also served as the impetus for NLP. As the treatment evolved, the developers focused increasingly on enhancing children's motivation and later recast NLP as Pivotal Response Treatment or PRT (Koegel et al. 1989, 1999).

Rationale or Underlying Theory

The rationale for the Natural Language Paradigm is largely derived from past research indicating that children with autism spectrum disorders often lack the motivation necessary to communicate or learn new skills (e.g. Dunlap 1984; Dunlap and Egel 1982). The intervention strategies, such as the use of reinforcers directly related to the communication (e.g., giving a child access to an item that he or she has requested), the reinforcement of all attempts to communicate, the frequent variation and sharing of tasks and stimulus materials, and the use of incidental teaching all are designed to contribute to increasing the child's motivation to interact and communicate with the therapist. The presumption is that, once the child understands, he or she is able to control access to a desired item or situation through initiating and responding to verbal communication, his or her motivation to use language increases.

Additionally, the developers of NLP regard each of these strategies as a key component of the language acquisition process that typically developing children go through. By refocusing the treatment on more naturally occurring speech interactions, rather than structured or didactic behavioral teaching methods, NLP aims to increase the generalization of language skills to settings outside of the clinic (Koegel et al. 1987).

Goals and Objectives

The intervention is designed to increase the child's use of spontaneous and appropriate language, encourage the generalization of these skills

to other settings, and increase social interactions and child-initiation of activities.

Treatment Participants

Ideal treatment participants meet criteria for autism as defined in the Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association 1994) and demonstrate severe language deficits and delays associated with the disorder. These children are generally classified as nonverbal, meaning they produce no spontaneous words or utterances, but may produce other types of vocalizations (Koegel et al.). The participants in the few studies specifically examining the NLP have been children between 4 and 10 years of age (Koegel et al.; Delprato 2001).

Treatment Procedures

NLP is designed as an individualized therapy that closely approximates the interactions and components present in a natural speaking situation. To accomplish this, the therapist presents a series of play trials using several stimulus items that have been previously selected by the child. These items are varied between trials and should be familiar to the child from his or her everyday environment. At the beginning of each trial, the therapist presents an item and then models appropriate verbal responses and play actions with the stimulus items to prompt the child to use speech. All of the child's attempts at verbal communication are repeated and expanded upon by the therapist and reinforced with praise and opportunities to play with the stimulus item.

Efficacy Information

Due to the relatively brief existence of the NLP in its original form, efficacy information is somewhat limited. In the original comparative study, each subject participated in both the analog teaching condition and the NLP condition consecutively. Koegel and colleagues reported that subjects, after treatment with the NLP, demonstrated “steady

and durable increases in both immediate and deferred utterances,” while these same subjects showed less, if any, improvement in these areas while in the analog teaching condition. More importantly, these gains were maintained and generalized to situations outside of the clinical setting by subjects treated with the NLP, but not by those in the analog teaching condition. Later studies comparing naturalistic language approaches to traditional behavior treatments reported similar results (Delprato 2001), which served to confirm the findings from the initial study by Koegel et al. However, because the studies on NLP have involved on a small number of subjects and focused on a very narrow range of communication skills, general conclusions cannot be drawn regarding the relative efficacy of NLP compared to other teaching approaches (Goldstein 2002, JADD).

Outcome Measurement

Treatment outcomes for the NLP intervention have most often been measured using spontaneous language samples, or “probes,” throughout the course of treatment. Probes assess the total number of utterances emitted by the child over a specified period of time and are conducted in a variety of settings, including intervention sessions, break periods, and during free play. The child's utterances are coded and categorized as one of three types: imitative, deferred imitation, or spontaneous (Koegel et al.).

Qualifications of Treatment Providers

In Koegel and colleagues' initial study, the clinicians administering the NLP intervention were supervised hearing and speech students with advanced training in behavior modification and language treatment.

Definition

Naturalistic interventions are behavior teaching procedures that occur in the context of naturally occurring activities (Koegel et al. 1987; McGee et al. 1984; Vismara and Rogers 2010). Intervention procedures embed teaching opportunities within the environment where the skills will be needed (Vismara & Rogers).

Historical Background

Individuals with an autism spectrum disorder exhibit deficits in communication, social interaction, and restricted and repetitive behavior (American Psychiatric Association [APA] 2000). Intensive early intervention programs have been shown to produce positive outcomes in a large percentage of the children diagnosed as having autism (Paul 2008; Harper et al. 2008). However, Carr (1983) reviewed behavior modification procedures for language instruction of children with autism and identified a weakness in many operant language programs. In intervention strategies employed in highly structured environments, treatment gains that were observed in the clinic

rarely generalized to other settings and behaviors were not often maintained (Miranda-Linne and Melin 1992). Many operant language programs also frequently resulted in cue dependency, rote responding, and little spontaneity of the target behavior (Miranda-Linne & Melin). Furthermore, treatment programs that did succeed in improving language skills required a great amount of time for even a minimal vocabulary (Koegel et al. 1987).

In response to these difficulties, many researchers investigated new behavioral interventions. In a study by Koegel et al. (1987), the effects of a traditional analog approach were compared to a natural language teaching condition (Koegel and Koegel 2006). The analog approach consisted of many successive trials, with each item chosen and presented by the clinician until the child reached a specific criterion (Koegel et al. 1987). In the natural language paradigm, procedures were modified to follow a more natural language-speaking situation and incorporated child choice, maintenance tasks, rewarding attempts to respond, and natural reinforcers directly related to the task (Koegel et al.). It was shown that children in the natural language condition had a higher rate and accuracy of correct responding, a greater increase in spontaneous utterances, and a greater generalization of language skills outside of the clinic setting (Koegel and Koegel 2006).

In 1986, the Congress issued a federal mandate PL 99-457 to provide early intervention for young children with disabilities in the least restrictive and most typical environments of the children (Kaiser and Trent 2007). Subsequent research has expanded the benefits of naturalistic interventions and has addressed the limitations of analog procedures that occur in highly structured settings (Koegel et al. 1987; Warren and Gazdag 1990). Data has shown that naturalistic interventions result in a higher generalization and maintenance of target behaviors (Barnet et al. 1993; Koegel et al. 1987, 1998; Miranda-Linne and Melin 1992; Vismara and Rogers 2010). These results have influenced current treatment programs to include procedures across multiple settings and within the child's natural environment in order to

effectively increase language, socialization, and behavioral skills for children with autism (Vismara & Rogers).

Rationale or Underlying Theory

Naturalistic interventions embed procedures in the context of naturally occurring activities and have shown to increase generalization, create more spontaneity, and improve the maintenance of the target behavior (Barnet et al. 1993; Ingersoll et al. 2007; Koegel et al. 1987, 1998; Miranda-Linne and Melin 1992; Vismara and Rogers 2010). As opposed to analog procedures that are directed by the clinician, involve drilling of the target behavior until acquisition is reached, and incorporate arbitrary reinforcers, natural interventions manipulate traditional variables (Koegel et al. 1987; Koegel and Koegel 2006). In naturalistic interventions, stimulus items are functional and chosen by the child, communicative attempts are rewarded, and natural reinforcers that directly relate to the task are employed (Koegel et al.; Koegel and Williams 1980; Miranda-Linne and Melin 1992). Procedures are implemented in the environment where the skills will be needed (i.e., the home, school, or community), so gains are rapidly produced, able to be generalized, and maintained after intervention (Brown and Odom 1995; Koegel and Koegel 2006; McGee et al. 1984).

Goals and Objectives

Naturalistic intervention procedures were developed with the following goals:

1. Embed treatment procedures in the context of naturally occurring activities and incorporate child choice, task variation, rewarding attempts, and direct and natural reinforcers to increase acquisition of language skills (Kaiser and Trent 2007; Koegel et al. 1987).
2. Improve the generalization and spontaneous use of target language skills across various settings and with typical peers and individuals

- in the child's daily routine (Hart and Risley 1975; McGee et al. 1984).
3. Increase the maintenance of treatment gains following intervention (Mirenda-Linne and Melin 1992).
 4. Create a nonaversive treatment program and improve the affect of children with autism and their treatment providers (Vismara and Rogers 2010).

Treatment Participants

Children with autism receive naturalistic interventions for deficits in social interaction, communication skills, and appropriate behavior (Williams and Williams 2010). A unique aspect of naturalistic interventions is the high level of participation of parents, paraprofessionals, and typical peers in the child's natural environment (Kaiser and Trent 2007; Kalyva and Avramidis 2005; Koegel and Koegel 2006). The procedures are designed for children with autism to receive treatment through interactions with individuals in their everyday life. Research shows that intensive intervention throughout the day is effective to increase the social, communication, and behavioral skills of children with autism; however, resources can be limited (Paul 2008). In order for children with autism to receive "round-the-clock" intervention services, the individuals that they interact with on a daily basis must be trained to implement treatment procedures (Barnet et al. 1993). In naturalistic intervention programs, parents, educators, and typical peers are trained in order to increase the quantity and availability of intervention across natural settings (Brown and Odom 1995; Koegel et al. 1996).

Parents are active participants in naturalistic interventions (Koegel et al. 1978, 1996). Research has shown that parents of children with autism can effectively implement behavioral, social, and communication procedures (Albert and Kaiser 1992; Koegel and Koegel 2006). Naturalistic treatment programs often incorporate a parent education component to teach caregivers how to employ intervention procedures and embed opportunities into the child's daily living routine

(Koegel and Koegel 2006). Effective parent participation can increase positive outcomes as well as have a collateral effect on family interactions (Koegel et al. 1996).

Paraprofessionals and typical peers are also significant contributors to natural intervention procedures. Increasing the inclusion of children with autism in regular classrooms and creating opportunities to engage in interactions with typical peers have been shown to increase the child's social development (Brown and Odom 1995; Fisher and Meyer 2002). In naturalistic intervention programs, teachers and counselors are trained in the treatment procedures and prompt typically developing children to engage in verbal interaction and social activities with children with autism (Koegel and Koegel 2006).

Parents, paraprofessionals, teachers, and typical peers all collaborate as key participants in naturalistic intervention procedures for children with autism.

Treatment Procedures

Naturalistic interventions use treatment procedures employed in the context of naturally occurring activities (McGee et al. 1984). Procedures are implemented in inclusive environments, and treatment strategies are embedded into everyday activities across multiple settings (Vismara and Rogers 2010). There are numerous teaching programs that use naturalistic interventions, and all incorporate the following procedural components or variations thereof. Treatment protocols take place in the child's natural environment (i.e., home, school, and community), and procedures are based on the foundation of child choice and the use of direct and natural reinforcers (Gillum et al. 2003; Kaiser and Trent 2007; Koegel et al. 1987, 1998; Koegel and Williams 1980). Common naturalistic methods to increase language acquisition are milieu therapy, incidental teaching, and pivotal response treatment (Hart and Risley 1975; Kaiser and Trent 1992; Koegel and Koegel 2006).

Naturalistic treatment programs are designed to fit each child's individual routine, and procedures incorporate child choice of stimulus

materials (Hart and Risley 1975; Kaiser and Trent 1992; Koegel et al. 1998). Child choice refers to following the child's lead and using child-preferred stimulus items, topics, toys, and interests (Koegel et al. 1999; Thiemann and Warren 2004; Yoder et al. 1995). Instead of the traditional approach in which the clinician arbitrarily selects a stimulus item, naturalistic procedures involve the clinician presenting stimulus items that the child selected from a pool of items (Koegel et al. 1987). The treatment provider uses the child's eye gaze, reaching, touching, etc., to determine the preferred items and uses those items in the intervention. Compared to the teacher selecting stimulus items, child choice of toys results in higher levels of engagement with toys, which creates a foundation from which more complex play behaviors can be taught (Reinhartsen et al. 2002). Furthermore, child choice has been shown to decrease problem behavior as well as increase autonomy (Reinhartsen et al.).

In addition to following the child's lead, naturalistic interventions incorporate direct and natural rewards (Koegel and Williams 1980; Williams et al. 1981). This means that the child is immediately reinforced with a reward that is directly related to the language opportunity (Koegel and Koegel 2006). For example, if the child makes an attempt to say "milk," then he or she will be immediately be given the milk so that a connection is made between their verbalization and the desired item (Koegel and Koegel 2006). This varies from the traditional approach which rewarded the child with an arbitrary item, for example, the child would receive an M&M's for any correct response that he or she provided (Koegel et al. 1987). This procedural component strengthens the connection between verbalizations and consequences (Williams et al. 1981).

Several natural interventions have been developed around the basic naturalistic treatment procedures for children with autism. Milieu therapy, incidental teaching, and pivotal response treatment all use naturalistic procedures to improve symptoms of autism (Hart and Risley 1968; Kaiser and Trent 1992; Koegel and Koegel 1996).

Milieu language intervention is a common naturalistic treatment that uses the procedures of

incidental teaching, modeling, mand-modeling, and time delay (Albert and Kaiser 1992; Warren and Gazdag 1990). Hart and Risley (1968a) developed the incidental teaching procedure to demonstrate the effectiveness of child-initiated interactions in treatment. Incidental teaching uses occasions when the child is verbally or non-verbally requesting materials or assistance as beneficial therapy opportunities (Thiemann and Warren 2004). Teachers, parents, or other children wait to prompt the child until he or she shows an interest by requesting or reaching for an object in the natural environment (Hart and Risley 1975). Once the child is interested, the opportunity exists for a model procedure, mand-model procedure, or time delay procedure (Albert and Kaiser 1992). A model procedure involves the adult producing a syllable, word, phrase, or sentence with the intention that the child will imitate the production (Albert and Kaiser 1992). Milieu therapy also uses the mand-model technique in which the adult presents a question or instruction for the child to verbalize within a naturally occurring context (Warren and Gazdag 1990; Yoder et al. 1995). Time delay is another procedure often incorporated into milieu therapy (Albert and Kaiser 1992; Yoder et al. 1995). Time delay involves the adult presenting a stimulus and then waiting anywhere between 5 and 30 s for the child's response (Mancil 2009).

Pivotal response treatment (PRT) is another naturalistic intervention model that targets pivotal areas of a child's development, such as motivation, responsivity to multiple cues, self-management, and social initiations (Koegel et al. 1999). Instead of targeting each individual behavior, PRT focuses on pivotal areas that when changed generally produce large collateral improvements in other areas (Koegel and Koegel 2006). Research has shown that improving the child's motivation level during treatment sessions can accelerate language learning, decrease problem behavior such as aggression and tantrums, and increase the affect of the child and the treatment provider (Koegel et al. 1997, 1987, 1998). PRT uses naturalistic and motivational procedures of child choice, task variation, interspersing maintenance tasks, rewarding attempts, and the use of

direct and natural reinforcers, with the overall goal of providing individuals with autism the social and educational skills to succeed in inclusive settings (Koegel and Koegel 2006). As opposed to the traditional analog approach that reinforces only correct responses, PRT broadens the reinforcement contingency so that the child is rewarded if they make a clear and direct attempt at the target behavior (Koegel et al. 1987). For example, if a child says “ba” instead of “ball,” he or she will be given the ball as a natural reward for their verbal attempt to communicate. PRT treatment procedures are used to teach language, decrease disruptive/self-stimulatory behaviors, and increase social, communication, and academic skills (Koegel and Koegel 2006).

In addition, floortime therapy, reciprocal imitation training, and positive behavioral support incorporate components of naturalistic procedures in their intervention techniques (Gillum et al. 2003; Ingersoll et al. 2007). Common treatment procedures used in these naturalistic intervention programs may include in vivo modeling, turn taking, shared control, priming, conversational recast, and self-management (Brown and Odom 1995; Camarata 1993; Gillum et al. 2003; Koegel and Koegel 1996; McGee et al. 1984).

Efficacy Information

Naturalistic interventions are effective in improving generalization across settings, increasing spontaneous speech, improving maintenance following intervention, and incorporating parents and teachers into the treatment program (Ingersoll et al. 2007; Koegel et al. 1987, 1998; Koegel and Koegel 1996; Koegel and Williams 1980; McGee et al. 1984; Miranda-Linne and Melin 1992). Traditional analog procedures succeed in increasing language, social, play, and behavioral skills of children with autism, but the effectiveness is limited in regard to generalization and maintenance of treatment gains (Vismara and Rogers 2010). Subsequent research has led to the formation of naturalistic interventions, which diminish the limitations of traditional approaches

and expand treatment procedures to the natural environment (Koegel et al. 1987).

A key benefit in implementing naturalistic interventions is the high level of generalization that occurs in the absence of special programming (Ingersoll et al. 2007; McGee et al. 1984; Warren and Gazdag 1990). Although analog procedures can create positive outcomes, the treatment gains frequently do not carry over to natural settings (Brown and Odom 1995; Camarata 1993). In naturalistic interventions, treatment takes place in already existing activities, so the child learns how to utilize skills in the environment in which they are needed (McGee et al. 1984). Procedures can be embedded into everyday activities such as the home, the classroom, and the community, and generalization of language gains does not require additional teaching programs (Hart and Risley 1975; Vismara and Rogers 2010). For example, Hart and Risley (1968) showed that traditional teaching procedures were effective in generating adjective-noun combinations in that restricted setting, but the child’s spontaneous vocabularies increased with the use of environmental contingencies. Furthermore, results from a study by Brown and Odom (1995) show that naturalistic peer interventions can easily be incorporated into a school setting and can lead to gains in socialization that can be applied across multiple settings.

Naturalistic interventions are also effective in improving the maintenance of treatment gains following intervention (Koegel et al. 1987). Miranda-Linne and Melin (1992) found that traditional methods can produce positive outcomes during home generalization probes, but the gains dissipated 1 week after intervention was completed. Incidental methods led to slower treatment gains, but the skills acquired were more permanent and continued to increase after teaching had been discontinued (Miranda-Linne and Melin 1992). A similar study found that generalization from trained to spontaneous language skills was maintained during a 4.5-month follow-up probe when teaching was provided in naturally occurring environments (Koegel and Koegel 1996; McGee et al. 1984).

Parents and families have found naturalistic interventions useful in expanding existing resources and reducing parental stress (Albert and Kaiser 1992; Koegel and Koegel 1996). According to Thiemann and Warren (2004), one of the primary challenges in treatment focused on communication is effectively implementing the intervention procedures into everyday practice. Including individuals in the child's natural environment (i.e., parents and teachers) can increase the intervention opportunities and the child's rate of progress (Barnet et al. 1993). In addition to improving and maintaining the child's treatment gains with the parent education component, families who implement naturalistic treatment procedures report higher amounts of leisure time spent together (Koegel and Koegel 1996). When parents are incorporated into naturalistic interventions, they show increased affect, more interest, lower levels of stress, and a positive engagement of communication with their child with autism (Koegel et al. 1996).

Naturalistic interventions are effective in increasing language acquisition, improving generalization and maintenance, and creating positive interactions for parents and family members with a child with autism.

Outcome Measurement

The National Standards Project has found sufficient evidence to show that naturalistic teaching strategies produce favorable outcomes for individuals on the autism spectrum. Through a systematic review of 32 studies, it was found that naturalistic strategies increase communication, interpersonal skills, learning readiness, and play behavior (National Autism Center 2009). With respect to age, naturalistic interventions demonstrate favorable outcomes for children aged zero to nine that have a diagnosis of autism or pervasive developmental disorder-not otherwise specified (PDD-NOS) (National Autism Center 2009).

A main diagnostic criterion of children with autism is deficits in communication and language skills (Mancil 2009). In 2009, the National Autism Center evaluated the literature and found

empirical support that naturalistic intervention procedures improve nonverbal and verbal methods of sharing emotions and information. Outcome measures have shown that children receiving naturalistic treatments can improve their speech intelligibility and functional use of target sounds during conversation (Camarata 1993; Koegel et al. 1998). Additionally, there is evidence that the intervention techniques are effective at increasing the level of responding and initiating communication in children with autism (Koegel et al. 2003).

Outcome measures also show that naturalistic treatment procedures improve interpersonal skills (National Autism Center 2009). Intervention strategies lead to increased play, social interaction, and assertions with peers (McGee et al. 1984; Stahmer and Ingersoll 2009; Vismara and Rogers 2010). Comprehensive social programs that embed natural procedures increase the level of appropriate conversation and peer interactions (Koegel and Frea 1993; Koegel et al. 2009). The National Autism Center also found sufficient evidence for support of treatment procedures as a method to increase learning success in complex skills.

Studies regarding natural intervention were rated high in experimental rigor, quality of the dependent variable, evidence of treatment fidelity, demonstration of participant ascertainment, and generalization of data collected. Thorough examination of naturalistic strategies by the National Autism Center has found empirical evidence to show that the intervention procedures produce positive gains in many core areas of autism and can be successfully implemented for children of many ages on the autism spectrum.

Qualifications of Treatment Providers

One key benefit of naturalistic interventions is the ease with which treatment providers can be taught to embed procedures into existing activities (Vismara and Rogers 2010). Treatment providers can be specialized therapists, members of the regular staff, or family members that are involved in

the child's daily life (Kaiser and Trent 1992; Kalyva and Avramidis 2005; Koegel and Koegel 2006).

Due to the fact that intervention procedures are typically employed in a setting outside the clinic, it is especially important that treatment providers are well trained in intervention strategies. Interventionists, whether they are students, parents, or consultants, must be proficient in the protocols and routinely be given feedback on their performance. In order to successfully implement intervention procedures, treatment providers typically receive training in the specific intervention that includes lectures, observations, role-play practice, and a written exam on policies and procedures (National Research Council 2001). Furthermore, some intervention programs require audiotaped or videotaped interactions that show the provider implementing the intervention with children (Albert and Kaiser 1992).

Treatment providers must meet fidelity of implementation in the intervention procedures in order for them to effectively employ the protocol. Treatment providers are typically trained in the intervention and then scored in vivo or through videotape by an observer. Fidelity of implementation is obtained when intervention procedures are performed correctly for a specified amount of time during the scoring period (Koegel and Koegel 2006). If intervention procedures do not meet the specified criterion level, then the trainer can identify areas that need improvement and may provide training on those specific components. Once the treatment providers are able to employ each intervention component at the specified level of fidelity, then they will be able to successfully perform the intervention with a child.

Feedback should be given on a routine basis for ongoing tracking of child progress and treatment fidelity. Supervision can take place by direct observation of the treatment provider interacting with the child, teacher-collected data, and videotaped samples of intervention sessions (National Research Council 2001).

In summary, naturalistic interventions reduce problems of generalization and maintenance. Further, they reduce family stress when compared to more structure intervention procedures. As such,

research suggests the importance of providing naturalistic interventions for children with autism.

Synonyms

Thiothixene

Definition

One of the first-generation neuroleptic (major tranquilizer) medications, thiothixene, is of medium potency. Like other agents in this class, its primary mode of action is through the dopamine neurotransmitter system. Compared to the newer, atypical neuroleptics (several of which have been approved for treatment of autism), these earlier agents were more likely to cause various side effects. These have been widely used for decades in the treatment of psychosis (particularly schizophrenia) but also have been used to treat maladaptive behaviors in autism (stereotyped movements, agitation, and self-injurious behaviors). Side effects of this medication can include muscle stiffness, dry mouth, weight gain, and a cluster of features often referred to as extrapyramidal symptoms (restlessness and movement problems that resemble some aspects of Parkinson's disease). Some of the side effects can be treated by anticholinergic agents like diphenhydramine. The most serious long-term side effect is tardive dyskinesia. Neuroleptic malignant syndrome is a rare but serious (and potentially fatal) side effect associated with fever, movement problems, and changes in mental state.

Definition

The need for in-home support for caregivers of children with ASD.

Historical Background

Prevalence rates of ASD have been steadily increasing for a number of years, and currently it is estimated that 1:59 children in the United States are impacted by ASD (Center for Disease Control 2019). Individuals with this disability have varying social-communication and behavior challenges. These challenges impact a person from infancy into adulthood and not only impact the quality of life of the individuals

themselves, these impairments also affect their caregivers and other family members (Gupta and Singhal 2004). Caregivers of children with disabilities have been widely studied in research, with a more recent intense focus on understanding how parenting a child with ASD specifically impacts the family (i.e., Ekas and Whitman 2011; Freedman et al. 2012).

Parents and guardians of individuals with autism spectrum disorders have significantly high levels of burden and stress in caring for their child (Goedeke et al. 2019). Research suggests that parents of individuals with autism experience both emotional and financial burdens (Krakovich et al. 2016). The financial burdens may vary across the lifespan, but for toddlers and school-age children, these financial hardships may be attributed to the cost of early intervention services, child care, medical expenses, or additional services not provided by the school district (i.e., private therapy services). Increased stress levels can be attributed to the level of severity of behavior and social-communication challenges of the child (Estes et al. 2009) and the financial costs associated with their care (Krakovich et al. 2016).

Historically, parents of individuals with ASD have reported higher levels of stress when compared with parents of children without disabilities or of children with other disabilities (Paynter et al. 2013). The stress of caring for a child with ASD has been found to trigger a number of adverse psychological reactions. The profound changes in families resulting from having a child with autism often lead to tension and stress. There are often anxious and depressive impacts on parents (Ben Soussia et al. 2017). Mothers of children with ASD have been studied more frequently than fathers, with reports indicating more stress, depression, and anxiety in mothers of individuals with ASD as compared to mothers of individuals with other disabilities (Davis and Carter 2008).

Parents have reported that this heightened tension has a direct impact on the entire family (Carbone et al. 2010). Freedman et al. (2012) identifies speculated reports that have indicated that parents of individuals with autism have a higher divorce rate (nearly 80%) than parents of

typically developing children. It is important to note that this statistic has not been substantiated in empirical research. Although an accurate divorce rate has not been identified, it is clear that marital relationships are impacted by raising a child with ASD (Freedman et al. 2012). While there is limited validated research on divorce rates of parents, it is important to acknowledge that parents and caregivers still require additional supports. Krakovich et al. (2016) identify examples of external supports as respite and formal ASD services and examples of internal supports such as education level and income.

Current Knowledge

A survey conducted by the State Department of Education in 2015 in Connecticut aimed to better understand the perspectives of parents of children with disabilities educated in CT schools. When looking at questions related to parent involvement and supports, 32% of parents did not know whether parent training opportunities existed within their district; more specifically, only 41% of parents with children with autism reported that they knew whether parent training opportunities existed within their district (Department of Special Education 2015). Additionally, only 39% of families of children with autism reported they were involved in a support network for families of children with disabilities, and only 44% of families of children with ASD reported they knew that parent support opportunities even existed (Department of Special Education). These findings indicate that services for parents do exist, but accessing the services is limited, which may be attributed to a variety of factors (i.e., location of supports, awareness of needs, finances, etc.). In another study (Carbone et al. 2010), parents report that although family supports are challenging to find, they were found to have positive results with these services (i.e., mental health services, parent and sibling support groups, and respite care). Additionally, parents reported that they had more positive experiences with informal parent-parent interactions (Carbone et al.). These findings indicate that there is a need to help parents identify quality

resources and supports that are available to them. Families rely on these informal and formal supports in order to help cope with caring for their child (Searing 2014).

Using education and training to empower families of children with ASD is best practice (Dawson-Squibb et al. 2019). The definition of parent training in ASD, however, is ambiguous due to the complexity of ASD and the number of areas that are targeted for intervention. After a review of the literature, Bearrs et al. (2015) suggest that parent training has a broad application in areas such as psychoeducation, care coordination, parent-mediated interventions for maladaptive behaviors, and core symptoms.

Future Directions

There is existing research exploring parent perspective of what their children need in terms of services and programming and findings pertaining to the increased levels of stress of families of children with ASD (Estes et al. 2009). However, there is still limited knowledge on the specific needs of the parents of children with autism. More research needs to be conducted to determine exactly what parents feel they need, what interventions are beneficial for parents, and how parents can gain access to available resources.

Historical data and current knowledge indicate that there is a need for caregiver support for families of children with ASD. It is imperative that other professionals help parents find the right support (Vernhet et al. 2019). For instance, local education agencies should understand the role that they have in supporting families. School districts can assist in identifying the specific needs of parents of students in their schools. Then districts can offer a variety of services and trainings for parents. Parent training can be offered as a related service in a child's individualized education plan (IDEA 2004). Offering training to meet the specific needs of parents can help with consistency of implementation of evidence-based practices used in school settings. Training

should also be provided through a variety of modalities (face to face, online webinars, presented in multiple languages, etc.). By having a variety of options, these trainings may reach a more diverse audience of caregivers (i.e., parents, grandparents, community members, babysitters, etc.). Additionally, if parents understand how to use these evidence-based practices, they can share these strategies with other caregivers. Training has been found to positively increase knowledge and skills of parents. Parent education of ASD and strategies can have a positive impact on stress levels (Tonge et al. 2006) and also improve family relationships.

Additionally, districts may need to market these services to parents in various ways in order to make sure families know what supports are available to them. These districts could collaborate with parent advocacy groups. Some research indicates that parents supporting other parents can help reduce stress levels (Dykens et al. 2014). Parent advocacy groups can help to offer assistance, programs, and support groups for other parents. Additionally, it will be vital for parent advocacy groups to continue to reach out in a variety of different ways to help support parents. These parent advocacy groups can reach out to parents within their network to inform them of trainings and programs being offered. Social media and webinars are also ways for parents to learn more about specific interventions, support services, and trainings.

Parents of children with ASD report that they do not have enough time for parental responsibilities or enough time for their romantic relationships (Hirsch and Paquin 2019). Programs should be more available to help caregivers find more personal time (Ekas and Whitman 2011). Respite care includes temporary caregiving services that can occur in the home setting. This may be an option for some families and can enable a parent to take a needed break from the daily responsibilities of raising a child with autism. However, it is important that people providing these caregiving services understand the challenges associated with autism (Goedeke et al. 2019).

Additionally, challenges associated with the degree of ASD symptoms the child exhibits are related to obstacles to engaging in family activities (i.e., eating out, vacations, etc.) (Hirsch and Paquin 2019). There is a need to help support families with parent training on strategies (e.g., Bearss et al. 2015). Additionally, these resources that are offered should be researched to determine if in fact they help reduce levels of stress within the home (Krakovich et al. 2016). Although predictors of stress have been identified, and recommendations have been suggested to help support parents, there is limited knowledge on which specific interventions have been reported to reduce parent stress levels (Krakovich et al.; Ekas and Whitman 2011) and improve the quality of lives of families with ASD. Further research should be conducted in this area in order to validate specific programs, training, or support that positively impact families of children with ASD (Goedeke et al. 2019).

response to a target stimulus in the presence of distracters. For example, participants may see two letters on a computer screen and be instructed to name the upper case letter (e.g., from May et al. 1995), e.g., “H” and “p.” In this trial, the participant would respond with “H.” Importantly, on a later trial, the letters might be “P” and “r.” The inhibition applied to “p” as a distracter on the earlier trial carries over into the current trial, when the “P” is now a target. This “negative priming” results in slower response times, i.e., people are slower to respond to targets that were previously distracters.

The effect need not be driven by exactly the same stimulus; it can be caused by targets occupying the same location as a prior distracter, targets sharing attributes or category membership with earlier distracters, or targets that require responses that were inhibited by earlier distracters. The negative priming effect is robust across a wide range of tasks.

Negative Priming Effect

Adam Naples

Yale Child Study Center, Yale University, New Haven, CT, USA

Definition

Negative priming is an experimental phenomenon hypothesized to reflect inhibitory aspects of executive function. Executive function encompasses complex processes such as planning, organization, reflection, and metacognition and more basic processes such as engaging and disengaging attention and initiating or inhibiting responses. Inhibition is a fundamental component of executive function and is thought to be captured by the negative priming effect on simple cognitive tasks.

The negative priming effect occurs in experiments where participants are required to make a

Definition

Negative reinforcement is a key principle in the behavioral theory of learning. Negative reinforcement is defined as the removal, reduction, or avoidance of a stimulus contingent upon a behavior, which results in an increased frequency of that behavior in the future. For example, a child who screams until an adult gives them a preferred item may negatively reinforce the adult's behavior. The termination of the screaming may serve as negative reinforcement for the adult's behavior of giving the child a preferred item when he/she is screaming. Negative reinforcement often involves the removal of an aversive stimulus, but it is not a requirement that the stimulus be undesirable. Negative reinforcement is similar to positive reinforcement in that both lead to increased responding in the future, but are dissimilar in that negative reinforcement involves the termination of a stimulus, and positive reinforcement requires the presentation of a stimulus. Negative reinforcement is typically confused with punishment; however, punishment results in a decrease in responding, not an increase.

Synonyms

[NEPS](#); [NEPS-U](#)

Definition

The title of this test, “NEPSY,” is not a true acronym but, rather, a combination of letters, across countries and languages that reflect the term “neuropsychology.”

Description

The NEPSY-II is a comprehensive neuropsychological battery for children aged 3–12. The test provides measures of sensor-motor, language, visuospatial processing, memory and learning, attention/executive functions, and social cognition. It is one of the few well-normed and standardized neuropsychological batteries for children and adolescents.

Similar to its predecessor, the NEPSY-II continues to be based on the theoretical foundation of Luria (1966) wherein designated brain functions correspond with selected assessment tasks. The neuropsychological domains covered by the NEPSY-II are clearly multidimensional and representative of the broad range of neurocognitive functions espoused by most neuropsychological models. Consistent with the NEPSY, the NEPSY-II includes the domains of Attention and Executive Functioning, Language, Memory and Learning, Sensorimotor, and Visuospatial Processing. Further, the NEPSY-II contains a new domain, Social Perception. This latter addition is innovative with respect to its inclusion in such assessment batteries, and provides an additional avenue for assessment from the neuroscience literature that has not been routinely available to most clinicians. These tasks also will be relevant for professionals conducting neuropsychological assessments for children and adolescents with autism spectrum disorder (ASD). It is important to note that the neuropsychological domains of the NEPSY-II are not empirically derived, or even statistically independent. Although this is clearly noted in the manual, the user is left to determine how specific subtests relate within and across domains and, importantly, how these relationships may change over the 3.0–16.11 age range proposed by the NEPSY-II. Specific subtests and their age range are provided below.

Domain/subtest	Age range
Sensorimotor	
Fingertip tapping	5–16
Imitating hand positions	3–12
Manual motor sequences	3–12
Visuomotor precision	3–12
Language	
Body part naming and identification	3–4
Comprehension of instructions	3–16
Oromotor sequences	3–12
Phonological processing	3–16
Repetition of nonsense words	5–12
Speeded naming	3–16
Word generation	3–16
Visuospatial processing	
Arrows	5–16
Block construction	3–16
Design copying	3–16
Geometric puzzles	3–16
Picture puzzles	7–16

The NEPSY and the NEPSY-II represent significant efforts to extend neuropsychological testing into the preschool years. Outside of selected intellectual batteries and single test approaches, there are few batteries that have attempted to

provide neuropsychological measurement for such a young population. This version of the test should facilitate increased precision with respect to description of neurocognitive functions for a wide variety of preschool children with both neurological and neurodevelopmental disorders and, subsequently, prescription of early intervention strategies.

Administration and Scoring

For the NEPSY-II, there is a separate *Administration Manual* that provides detailed, manualized procedures for administration and scoring of each subtest. The domain, description, materials, starting points, discontinue rule, timing, recording, general guidelines, and specific administration and scoring details are provided for each subtest. These details are particularly important for several subtests, such as Clocks, Design Copying, Visuomotor Precision, and Word Generation, where increased attention to detail in administration and scoring is required. The materials provided in the NEPSY-II kit are easy to use, colorful and attractive, and appear to be relatively durable. Separate test forms are provided for the preschool battery (ages 3–4) and the school-age battery (ages 5–16). There also are additional teaching items, which should facilitate assessment to children with ASD.

One modification asserted for the NEPSY-II was to provide increased flexibility in the order of subtest administration. Although this was present in the 1998 version of the NEPSY, it was not clear how different orders of subtest administration would affect scores in a larger test profile. For the NEPSY-II, the test developers examined the flexibility systematically via four different administration orders during the standardization process. By not showing any order effects, they were successful in being able to document that the subtests in the NEPSY-II could be administered in a variety of orders without affecting results. This should facilitate subtest administration, particularly in difficult-to-test samples of children (e.g., child psychiatric disorders, ADHD-Hyperactive Type), and this benefit will extend into both the clinical and research realms.

Scoring procedures for the NEPSY-II subtests are clearly presented in the *Administration Manual*. While most of these can be calculated manually, the efficiency of their use likely will increase with use of the NEPSY-II computer scoring program. To obtain the various scores on the NEPSY-II, however, the *Clinical and Interpretive Manual* also will be needed as this is where the normative tables are located. If the computer scoring program is utilized, it will be important for the examiner to consult the *Clinical and Interpretive Manual* to determine how to use these scores, especially when employing the various contrast scores and behavioral observations that can be calculated. The deletion of the NEPSY domain scores should facilitate the scoring process, but it will require additional knowledge with respect to how various subtests interrelate for a selected clinical population of interest. Unlike many intelligence tests, an overall score is not calculated.

Interpretation

Just like other neuropsychological assessment approaches, the interpretation of the NEPSY-II requires a certain amount of examiner knowledge with respect to brain functioning and, at a minimum, a knowledge base in the underlying neurocognitive functions of selected conditions. So, while this battery can be administered by many different psychological examiners, its interpretation does require additional knowledge that will facilitate its use and clinical utility across settings and patient populations. This will be especially pertinent to the nonneuropsychologist who may be working with the complexities inherent in a population of children and adolescents with ASD.

Historical Background

The American version of the NEPSY was published in 1998, with approximately 10 years of development going into its evolution. This version of the NEPSY included 36 subtests arranged across five major neuropsychological domains based on Lurian Theory: Attention/Executive Functions, Sensorimotor, Language,

Visuospatial, and Memory/Learning. The test had normative data that extended from ages 3.0 through age 12.11, with selected tasks being devoted to preschoolers (3.0–5.11) and school-age children (ages 6.0–12.11), with an array of different scores being available to assist with interpretation (e.g., standard scores, percentile ranks, age equivalents). This version of the NEPSY, along with its Scandinavian counterparts, provided one of the first well-normed neuropsychological batteries for children.

The NEPSY was developed out of a specific professional need; that is, the lack of adequate, developmentally appropriate neuropsychological assessment tools for children. Dr. Marit Korkman, a Finnish pediatric neuropsychologist, assembled a variety of tasks into a brief neuropsychological assessment for children 5 through 6 years of age – the NEPS. This seminal version of the NEPSY was subsequently revised by expanding the scoring from a pass/fail criterion assessment measure to allowing for standardized age-based scores for children from ages 3.6 to 9.5. This set of tasks was called the NEPS-U in Finland and the NEPSY in English. Similar versions of the NEPSY were published in Sweden and Denmark, with the current version, the NEPSY-II, appearing in 2010.

Psychometric Data

Standardization

The normative sample was extracted from the most recently available census data, with excellent concurrence with the available census figures with respect to race/ethnicity, parent education, and geographic region of the country. The minority representation was noteworthy across nearly all of the stratification cells. The NEPSY-II also was stratified by chronological age and evenly divided by gender. More specifically, the NEPSY-II was standardized on 1200 children across the ages of 3 through 16 years. Of the 29 possible subtests included in the standardization, 17 were administered to children ages 3–4 years; children 5–6 years of age were administered 22 subtests and 2 delay tasks; children ages 6–12 years were given 23 subtests

and 2 delay tasks; and the adolescent children ages 13–16 years received 24 subtests and 3 delay tasks.

Despite these efforts, a number of NEPSY subtests were not included in the current standardization, but were still included in the NEPSY-II. These subtests were not included in an effort to shorten the time required for a child to complete the standardization battery, but also because the development team determined that the targeted tasks required no modifications and likely would show little change in normative values. Consequently, these subtests (i.e., Design Fluency, Oromotor Sequences, Repetition of Nonsense Words, Manual Motor Sequences, Route Finding, and Imitative Hand Positions) were not included in the standardization version and, for the NEPSY-II, retained the normative scores from the 1998 version of the NEPSY.

Reliability

The area of reliability is critical in test construction as not only does it determine the test's capabilities of replicating results, but it also sets the upper limit on validity. For the NEPSY-II, most subtests have adequate-to-high internal consistency estimates, and the standard error of measure for all of the subtests ranged from 0.85 to 2.18 across all of the age ranges. Temporal stability of the NEPSY-II subtests across six age groups (i.e., ages 3–4; 5–6; 7–8; 9–10; 11–12; and 13–16) revealed little change in scores over an average of a 3-week period (range 12–51 days), suggesting that there was little practice effect across a relatively short time frame. This is critical in a test where alternative form reliability is not available, and provides an evidence-based foundation to use many of the subtests in various types of intervention studies. Given the potential application of the NEPSY-II to children with ASD, it is important to note that the reliability estimates of the subtests were relatively stable for both typical and clinical samples.

Although not directly related to reliability, the issue of tests floors and ceilings can have a direct effect on reliability by potentially restricting the range of scores available. This is especially important for both lower and higher functioning

individuals on the autism spectrum. For the NEPSY-II the test developers focused significant resources on improving the test floors. This is absolutely critical for a test that is designed to uncover neurocognitive weaknesses across different presenting problems and disorders. In this regard, nearly all of the NEPSY-II subtests across the age bands have at least a two standard deviations limit; that is, a child or adolescent can continue to show test variability even when the items begin to become too challenging for them. An adequate floor is essential for differentiating the nature and severity of weaknesses. There is a difference across the age range, however, with all or nearly all of the subtests having an adequate floor from ages 9.0 to 16.9, but 5 to 13 of these subtests not having an adequate floor for ages 5–13 years. In general, the number of subtests having at least a two standard deviation floor increases with age. Conversely, the test developers were not as focused on having at least a two standard deviations ceiling on the subtests. Although this is consistent with the notion of assessment via the NEPSY-II, this is unfortunate as it may place a limit on determining the presence of neurocognitive strengths; consequently, the concept of utilizing neurocognitive strengths to facilitate intervention may be limited. This notion is apparent in the NEPSY-II normative data as from ages 3.0 to 5.9, few subtests meet this criterion (0–5 subtests); from ages 6.0 to 9.9, only 3–8 subtests meet this criterion; and from ages 10.0 to 16.9, only 11–17 subtests meet this criterion.

Validity

Content validity procedures produced a battery of tasks that adequately sample the targeted constructs of interest. For construct validity, the NEPSY-II provides an interesting challenge, in that while there appears to be an overarching set of neuropsychological domains (e.g., Language, Visuospatial Processing, and Social Perception), the test is not designed to provide scores for these domains. As such, and in accordance with the guidance in the Clinical and Interpretive Manual, the administration and interpretation of the NEPSY-II should be guided by the subtests. Consistent with this philosophy, the NEPSY-II

continues to focus on the subtests and their interrelationships. For the NEPSY-II, a multitrait-multimethod correlational model demonstrated support for construct validity across both typical and clinical samples. Although previous efforts to examine the factor structure of the 1998 version of the NEPSY (Mosconi et al. 2008; Stinnett et al. 2002) provided mixed support for the NEPSY, it is unfortunate that these additional analyses were not explored. In support of the test developers' contentions, however, it is likely that different factor structures would be present across different clinical groups, much as is seen in the pattern of intercorrelations of subtests between clinical samples and the normative sample, and this question will require ongoing examination.

Further, with an ongoing emphasis on test interpretation at the subtest level, it would have been beneficial for each task to have accompanying subtest specificity estimates (i.e., an index for what proportion of a subtest's variance is unique to the subtest and reliable). This would have facilitated interpretation and utilization of the subtests in the way they were intended, but with empirical evidence as to their ability to measure a specific function. Criterion-related validity was determined primarily by using concurrent validity studies (i.e., the relationship of the NEPSY-II with other tests measuring similar constructs) wherein good correlations were obtained (e.g., NEPSY-II Memory and Learning subtests correlated most highly with selected subtests from the Children's Memory Scale).

Taken together, these findings support a convergent validity line of evidence for the NEPSY-II; however, it is important to note that these patterns of correlation may change depending on the age of the child, the presenting clinical condition, and the method of assessment (e.g., parent rater, clinician ratings). Additionally, few empirical data are available with respect to the utility of the preschool battery for the NEPSY – either from the publisher or independent investigators, and the same seems to be true with respect to the release of the NEPSY-II. The field will need to determine the ultimate clinical utility of the preschool version of this test, particularly for very young children suspected of being on the autism

spectrum. This issue will require additional examination as the NEPSY-II begins to be employed in a variety of clinical settings, particularly with the wide spectrum of cognitive and behavioral manifestations seen in ASD and the movement toward earlier diagnosis.

Clinical Uses

Clinical Application to ASD

Similar to its neurocognitive predecessors, including the NEPSY, the NEPSY-II utilized available data to showcase its utility with both neurological and neurodevelopmental disorders. The utility with neurological disorders continues the long-standing standard of use of such tests and procedures with frank neurological conditions, but the inclusion of neurodevelopmental disorders – conditions that presume neurological involvement (e.g., ASD) – clearly expands the overall application of this test to a wide variety of potential clients. To facilitate this process, the manual proposes eight different referral batteries from which to facilitate subtest selection.

One of those suggested batteries pertains to children with autism, or suspected of being on the autism spectrum. Suggested tasks span all six of the NEPSY-II neurocognitive domains and include Attention/Executive Functioning (Statue, Design Fluency, Auditory Attention and Response Set, Inhibition, and Animal Sorting); Language (Comprehension of Instructions, Speeded Naming, Word Generation, and Phonological Processing); Memory and Learning (Memory for Designs and Delayed Recall, Narrative Memory, Memory for Faces and Delayed Recall, and Word List Interference); Sensorimotor (Imitating Hand Positions, Visuomotor Precision, Manual Motor Sequences, and Fingertip Tapping); Social Perception (Affect Recognition and Theory of Mind); and Visuospatial Processing (Block Construction, Geometric Puzzles, Design Copying, Geometric Puzzles, Arrows, and Picture Puzzles).

Special Group Studies

The special group studies conducted with the NEPSY-II are noteworthy in that the test developers employed 10 different clinical conditions.

Comparison groups were derived from the normative sample and matched on chronological age, gender, race, and parent education levels. These studies have promised to determine the differential sensitivity of the NEPSY-II to the neuropsychological profiles that can be manifested by specific disorders. Findings from these special group studies generally support the clinical utility of the NEPSY-II in the assessment of children referred for different conditions and disorders. More specifically, the special groups typically differed from the typical groups on variables where they would be expected to deviate, as well as in a wide range of other variables. For example, children with intellectual disabilities and ASD performed more poorly than the typical group on nearly all of the NEPSY-II subtests. The separate examination of the newly added Theory of Mind Subtest for the ASD versus Controls, and for the Asperger's Disorder versus Controls, also provided support for the use of this subtest with these types of clinical referrals. Although useful, these group comparisons should be carefully considered, given their limitations (e.g., small sample sizes, inclusion/exclusion criteria, comorbidity, etc.) until more independent, contemporary data on the use of the NEPSY-II emerge over time.

Empirical Findings in ASD

With the original NEPSY, there were a number of studies that were conducted with samples of children and adolescents with ASD to demonstrate its ability to differentiate between various neurocognitive functions as well as between different diagnostic groups (Hooper et al., 2006; Joseph et al. 2005; Kjelgaard & Tager-Flusberg, 2001; Planche & Lemonnier, 2012). Since the emergence of the NEPSY-II in 2010, there have been a number of studies that have utilized this revised set of procedures for children with ASD. Several studies have demonstrated the utility of the NEPSY-II in differentiating the cognitive abilities of children with high functioning ASD. Narzisi et al. (2012) compared the neurocognitive performance of 22 children with high functioning to 44 healthy controls matched by age, race, gender, and maternal education. Results indicated the presence of significant deficits in Attention and Executive Functions, Language, Learning and

Memory, and Sensorimotor Processing, with only Visuospatial Processing being similar to healthy controls. Further, Narzisi et al. found the expected Theory of Mind deficits in the ASD sample, but this was noted only in the verbally-based tasks. Barron-Linnankoski et al. (2015) conducted a similar study for children, ages 6 to 11 years, and reported the high functioning ASD group to show relative strengths in their verbal reasoning and the expected weaknesses in tasks reflecting cognitive flexibility, verbal fluency, and narrative memory.

In addition to these emergent studies showing the utility of the NEPSY-II with children with ASD, another important trend that is surfacing is the use of the NEPSY-II subtests in interventional science as targeted outcome measures. Specifically, Young and Posselt (2012) used the Affect Recognition Subtest as one of the outcome measures of their examination of The Transporters DVD as a learning tool for children with ASD, aged 4–8 years of age. In addition to their positive findings overall, the NEPSY-II Affect Recognition Test performed well in this intervention, showing positive changes from pre- to posttest over the course of a 3-week trial. Using the same intervention, Williams et al. (2012) used the Affect Recognition and Theory of Mind subtests as outcome measures for their trial. Both NEPSY-II tasks performed well in this 4-week intervention, which also included a 1-month post-intervention follow-up.

Conclusion

The NEPSY-II is one of the few well-standardized and normed neuropsychological batteries for children. The NEPSY-II has benefited from a long developmental history, with the most recent revision capitalizing on the most contemporary findings in child neuropsychology. Changes to the NEPSY-II in terms of its content and administration should provide a fruitful avenue for neuropsychological assessment of children with an existing ASD diagnosis and those suspected as being on the spectrum. The NEPSY-II maintains good psychometric properties, and its use with children and adolescents with ASD has begun to

surface. These findings have demonstrated its clinical utility in detailing relative strengths and weaknesses in neurocognitive functions in individuals with ASD as well as in differentiating between different clinical groups. Importantly, subtests of the NEPSY-II have begun to be used in interventions, and the selected tasks have performed well with respect to the obtainability of reliable data and being sensitive to changes secondary to the targeted intervention. It is important to note that while the NEPSY-II will not provide information on the specific diagnostic symptoms of ASD, it will compliment ongoing diagnostic efforts by characterizing the neurocognitive manifestations of ASD in an individual child, and the emergent empirical literature has begun to show this to be the case. This neurocognitive profile should prove useful in educational planning and cognitive remediation efforts, assisting in how to structure other interventions (e.g., specific therapies, social interactions, etc.), and using the NEPSY-II and its subtests as targeted outcome measures for interventional science.

Netherlands and Autism, The

Jan Rutger Van der Gaag
Department of Psychiatry and Karakter
University Center for Child and Adolescent
Psychiatry, Radboud University Medical Centre,
Utrecht, Netherlands
Stradina University of Riga, Riga, Latvia

Historical Background – Legal Aspects – Current Practice

Van Krefeld introduced the concept of autism in the Netherlands in the 1950s from Leiden who, interestingly, referred both to the work of Kanner as well as to that of Asperger! And

though the work of the Creak party and Lotter and Rutter was known in this country, most of the research and clinical practice focused on what was then referred to as “developmental psychosis” (Utrecht: Profs Kamp, Van Engeland). At the end of the 1970s, the primacy of psychoanalysis in child and adolescent psychiatry was replaced by a far more scientific and empirical and pragmatic approach. The introduction of DSM III had a great impulse on the scientific approach spread over the country: Rotterdam Epidemiology (Frank Verhulst) Utrecht Developmental Disorders Autism and ADHD and Multiplex Developmental Disorders (Herman van Engeland) and PDD-NOS Groningen (Ruud Minderaa). The greatly inspiring and dynamic Donald Cohen closely linked the two latter centers with Yale Child Study Center, thus encouraging a fruitful transatlantic cooperation.

At the same time, parents of children with autism joined forces and in the late 1970s started the Netherlands Autism Association (NVA). At the start it was only a small group of parents of severely impaired children. They did not rest before the 1984 Autism Bill was passed in parliament acknowledging that autism is a serious developmental disorder and a great burden on families. The bill states that individuals with autism and their families should be entitled access to relevant services and remuneration of necessary care and educational services.

The Bill on Autism assumed that the prevalence of autism would hover around 5/10,000 as the epidemiological finding by Lotter suggested, though the prevalence in the Camberwell Study (1979) adding up to 30/10,000 was precluded. The “passport” to access special education, specialized services, or social benefits for handicapped people was set as a DSM diagnosis of autism or PDD-NOS. The social benefits include a so-called “Personalized Budget” (PGB). This is community funded and may add up to € 80,000 per year. The patient/parents may submit a budget including the salaries for those that will provide the support they/their child requires. To date no systematic epidemiological studies have been undertaken in the Netherlands, and it is assumed that the prevalence will be in line with

those of our neighbors with an estimate of around 1% in the total population (Baird et al. 2010). Yet figures from primary education show that nearly 1.4% of the pupils are coined as “leaners with special needs” having received a diagnosis of “autism spectrum disorder” according to DMS V. Likewise, the prevalence of autism in Eindhoven (cradle of high-tech industry) is much higher (2.3%) than in other Dutch towns like Harlem (0.84%) and the university town Utrecht (0.57%). This finding or skewed repartition is in line with findings of higher prevalence of ASD in, e.g., Silicon Valley and Cambridge.

The National Health Council produced two cardinal reports: the first one in 2009 “Autism: a life-long *different*” (<https://www.gezondheidsraad.nl/taak-werkwijze/werkterrein/optimale-gezondheidszorg/autismespectrumstoornissen-een-leven-lang-anders> with a summary in English.) pointed attention to the increasing amount of adults and also the underdiagnosed group of girls and women along with the observation that as modern society speeds up and requires a great flexibility, individuals with ASD are more at risk in schools, universities, and the workplace. This report was followed in 2012 by the report “*Knowledge Infra-structure for Autism Spectrum Disorders*” (https://www.gezondheidsraad.nl/sites/default/files/201209_1.pdf with a summary in English.) notifying the Minister of Health that expertise in the field of Autism should be present in centers countrywide and knowledge on autism spectrum disorders should become available to experts as well as to the general public. Since 2012, multidisciplinary Guidelines are available for professionals and the general public. These address the diagnostic issues as well as the evidence of stimulation, treatment, and support programs. In 2014, the secretary of State for (Mental)Health launched a working group called: “*Autism: insiders views*.” In this working group, {adult}patients and parents of children and adolescents with autism spectrum disorder addressed sixty bottlenecks within the homecare, educational system, leisure time, respite care, working-place offering comments from hand-on experts, and making suggestions for improvement, changes, and innovation. The working group after termination of its advices to the government has pursued its activities in a

coalition “*Taking the perspective of the person with autism*” including more than a hundred patients with specific expertise on one of the sixty issues that from their point of view merit investment and improvement.

Early Detection and Intervention Programs

Many parents with a child with a developmental disorder, e.g., autism, have endured a painful endeavor, being referred from one professional to the other most often with the meant as reassuring news “we cannot tell precisely yet. . . so let us wait and see how your child develops, before getting a proper diagnosis and adequate help.” Extremely frustrating for parents and detrimental for their child as precious time when adequate stimulation could have made a difference. So, very understandably, parents that have had that frustrating experience call for early detection in order to prevent others going through the same nightmare as they themselves.

Three different approaches have been set up to date. SOSO (translated: Screening and Assessment of Social Development) (Publications between 2006 and 2007.) was conducted by the department of Child and Adolescent Psychiatry from the University Medical Centre in Utrecht. It was ambitious in the sense that it aimed at diagnosing children with autism as early in life as possible. The population was a year birth cohort including 30,000 newborn children all screened at the age of 14 months at the community pediatric consultations attended by 99% of all newborns in our country. Parents were asked to fill in a questionnaire, the ESAT (Early Screening for Autistic Traits). When enough “red flags” pointed at a deviant development, the parents were offered a home visit by a trained psychologist and if through direct observation the suspicion was confirmed a thorough assessment with ADOS, ADI, and neuropsychological and neurological/psychiatric assessment followed. The lessons learned were that many parents were reluctant to accept the invitation (though at a later stage they all sought help for their child). A second project

built on these experiences and was called the DIANE (Publications between 2008 and 2011.) (DIagnosing Autism in the NEtherlands) project (Nijmegen area). The team here took a slightly different approach. Community pediatricians were trained to enhance their awareness for autism in very young children. When they detected such a child in their Baby-Wellbeing clinics (attended by 98% of all the children born in the Netherlands), they signaled this. The ESAT was now performed during a home visit where the psychologist observed the child while interviewing the parents. After the formal assessment in the university clinic, the parents were offered a home-based intervention: an interactive program in which parents were trained in better acknowledging the child's messages and needs and to meet them of to discipline them in a far more effective manner. Yet the program was not successfully implemented as the essence lies in the continuous training of the grassroots workers and the involvement and motivation of parents. The third attempt is on its way with yet a more elaborated approach. The Papageno Foundation (Jaap & Aaltje van Zweden) has joined forces to develop a nationwide early detection and intervention network for parents that have concerns about the development of their child. Twenty-two teams of professionals involved in early intervention in autism have joined forces and coordinate their assessment programs in order to offer the same program through the whole country. Moreover, experts in different fields of autism are prepared to give videoconference consultation anywhere in the country to the parents at professionals request. This is aimed at making sure children and their families get the best possible treatment near to their homes. The parents manage the child's file and provide access to all professionals involved. The file is part of a secured electronic environment where forum conversations can take place addressing any questions relevant for any of the participants, thus making parents less dependent on their professional support team. Finally, the network includes a database where all that involved have access to all the relevant literature (with annotations of evidence and relevance). Finally, every referral leads to the home visit, as soon as possible, by a trained

professional who provides a home-based basic intervention to help parents cope with the basics of helping their child given its peculiarities. At the same time, this intervention provides opportunity to observe the child and thus determine which assessment of medical examination would prove most valuable for this child in its social and family context. The first two pilot regions are currently active; further implementation will follow in 2018.

Current Treatment and Centers

Throughout the whole country alongside all university clinics, both mental health institutions and psychologists and psychiatrists in private practice are well knowledgeable of the diagnostic and treatment/guidance needs of individuals with autism spectrum disorders and their families and close dear ones. There are guidelines for all phases of development. And just like the network for early detection and intervention, there are networks for adults with autism (CASS 18+) and a special network for autism in women and girls (Women Inc. and FANN). Finally, adults with autism spectrum disorder are well organized in an own organization (PAS) that offers advice and combats stigmatization in the workplace.

Education and Autism Spectrum Disorders

A DSM classification of ASD qualifies those children as a learner with special needs. Extra support can be given in the classroom in a regular school both for remedial teaching or addressing challenging behavior or anxieties in the classroom/playground situation. But if necessary, the Dutch education system includes special schools in different categories. Learners with autism can be helped in so-called Cluster 2 schools for learners with hearing, speech, and communication problems; Cluster 3 schools for learners with developmental delays; and finally cluster 4 for learners with emotional and/or conduct problems. The beauty of the system is that it offers specific

support or a secure environment for children and adolescents with autism spectrum disorders regardless their intellectual capacities. The vulnerability of a system is much adapted to the peculiarities that it makes integration in the “real world” where individuals with ASD will to a certain degree have to adapt to less ideal situation, more difficult.

Autism and Comorbidity

Specialized Centers for Autism (e.g., Centrum Autisme Leiden (<https://www.rivierduinen.nl/autisme>) and/or Centrum OntwikkelingsStoornissen (Centre for Developmental Disorders) Dimence GGz Deventer (<https://centrumontwikkelingsstoornissen.dimence.nl/>)) and the University Clinics offer countrywide consultation for (Mental Health) professionals encountering difficulties in coping with and offering adequate treatment for individuals with autism with comorbid conditions ranging from learning disability, cerebral palsy, psychosis, depression, addiction, etc.

Overview of Research Directions

The Netherlands has a solid track record in autism research in a great variety of areas. These include taxonomy, neuroimaging, and electrophysiology as well as neuropsychological studies. Strangely no countrywide epidemiological studies have been conducted in the Netherlands, though some studies suggest that the prevalence of autism spectrum disorders may be quite high.

Social Policies

Healthcare in the Netherlands is undergoing a profound change. More and more healthcare is integrated with (social) welfare. Healthcare is supported by a national insurance scheme in which all citizens are enrolled for reimbursement of basic healthcare. If one cannot afford it, the social welfare provides assistance. Social welfare is provided by the municipalities, which

are responsible for the well-being of their inhabitants. Care for people with a handicap or chronic condition is offered in various manners: they can receive support given according to national guidelines either from healthcare agencies of welfare providers. They can also opt for a “Personalized Health Budget.” The individual, his parents, or legal mentors present a budget plan including the cost of help and support they estimate required for the well-being of the individual concerned and for which budget they are accountable year after year.

The national report “Autism: a lifelong *different*” also looks into the requirements for education, meaningful daytime activities, and preferably integration in paid labor.

Finally, individuals with autism spectrum disorder, can from their 18th birthday on, benefit from an invalidity pension provided by the state (WAJONG: “invalidity bill for youth”) that will support them lifelong, and is interrupted if the individual finds paid work.

Tentative Conclusions

Autism spectrum disorders are quite a common problem in the Netherlands. Despite the absence of any systematic epidemiological data, the figure of 1.4% learners with ASD in primary education reflects a high prevalence of autism spectrum disorders in this country.

Along with a nationwide network for early detection, services for individuals with ASD and their families are well organized. Social welfare and health insurance provides the necessary support.

Network Coherence

► Brain Connectivity Theories of Autism

Neural Mechanisms in Autism

Manuel Casanova

Department of Psychiatry, University of
Louisville, Louisville, KY, USA

Definition

Minicolumns are elemental anatomical and functional modules of the neocortex that serve as cytoarchitectural templates for the arrangement of cells and their connections. A chain of excitatory neurons, along with their axonal and dendritic bundles, constitutes its core. These excitatory neurons extend radially, i.e., perpendicular to the neocortex, through layers II to VI. Among other anatomical elements present at the periphery of the minicolumn are (a) synaptic elements which integrate translaminar connections and (b) interneurons that provide for a vertical sheath of surround inhibition to the information being processed by the core. The minicolumn exhibits variability between different brain regions, across hemispheres within a given brain, as well as among individuals within and across species. Nevertheless, the basic organization of microcircuitry is maintained throughout the cortex of all mammals (Buxhoeveden and Casanova 2005; Douglas and Martin 2004).

Historical Background

The neocortex covers the massive network of myelinated fibers in the white matter like the crust on a camembert, yet the vast majority of connections in the brain are not provided by corticocortical projections in the white matter. The majority of cortical connections take place between neighboring cells in a dimensional scale spanning only a few microns. These connections are typically contained within stereotyped microcircuits which are distributed iteratively throughout the cortex. Early neuroanatomists, like Cajal and Meynert, were among the first to describe the anatomical skeleton of these circuits when they noted the distribution of pyramidal cells in recurring arrays perpendicular to the pial surface (DeFelipe 2005). von Economo and Koskinas called them “radii” as they paralleled the radial arrangement of white matter bundles within the cortex (von Economo and Koskinas 1925). Other distinguished neuroscientists further defined the anatomy of these modules as consisting of a pyramidal cell column core with synaptic elements and inhibitory interneurons at its periphery (Peters and Sethares 1991, 1996; Szentágothai 1978). It is now known that these circuit arrangements, termed “minicolumns” by the pioneering neurophysiologist Vernon Mountcastle, feature a polarity in which information ordered by evolution and development is represented in the topographical pattern of minicolumnar inputs directed vertically toward inputs from across the cortex (Casanova 2008a, 2010; Casanova and Tillquist 2008; Mountcastle 1998).

Although the presence of these vertical arrangements cannot be questioned, a functional role was never suggested or described by early researchers. It was not until the late 1930s that these anatomical units acquired physiological significance as elementary units of information processing. Based on his experience with the Golgi silver impregnation technique, Rafael Lorente de Nó (1938) proposed the existence of clusters of cells arranged in vertical modules that applied canonical operations on thalamocortical and corticocortical inputs. This idea receives some anatomical support from the fact that the

neocortex unvaryingly uses layers II and III for association (e.g., corticocortical integration), layer IV for reception, and layers V and VI for efferent connectivity. The work of Lorente de Nó antedated our current understanding of computer science wherein a single logic gate (i.e., NOR or the minicolumn in our case) in different configurations can provide for higher-level functions capable of implementing any computer program (Casanova et al. 2003). During the last few decades, many authors have revived and expanded de Nó's idea of a canonical neocortical circuit (Creutzfeldt 1995; Douglas and Martin 2004).

Current Knowledge

The advantage of short, stereotyped microcircuits contained within minicolumns is that patterns of information can be represented by synchronous outputs coordinated among units. The white matter connections linking distant cortical areas are sparse thus providing a “small-world” architecture which minimizes wiring. The end result is a balance between neural clusters and wiring that minimizes connection steps between local circuits across the neocortex. In effect, most neurons maintain short connection lengths within clusters that themselves are linked by longer range projections. The preferred clustering configuration for neurons within the neocortex is the minicolumn (Casanova 2010).

Ontogeny

Pyramidal cell arrays are derived from the primordial neuroepithelium, i.e., progenitor cells that attach themselves both to the ependymal (ventricular) and pial surfaces. Their epithelial origin is betrayed by the presence of tight junctions within their end feet which together constitute a pia externa glia limiting membrane. The dividing neuroepithelium provides for migrating neuroblasts that wedge themselves between the first (primordial) lamina and the subplate. Neurons fated for the infragranular layers are thought,

during asymmetric division, to inherit the pial fiber from the radial glial cell, which then allows the neuroblast to translocate into the lower layers of the cortical plate. In contrast, neural progeny meant for superficial cortical layers attaches and locomotes along the radial glial scaffolding until the neuroblast's pial-directed extension reaches the marginal zone, at which point it disengages from the radial glial scaffolding and finishes its journey via somal translocation (Casanova et al. 2009; Williams and Casanova 2011a). As neuroblasts lose their glial attachment, they begin to mature into pyramidal cells having as a common characteristic their attachment by their apical dendrites to the first lamina. In humans, the cortical plate starts to form at approximately the 7th week of gestation and is almost completed by the 15th week of gestation (Marin-Padilla 2011). Interneurons are later on coupled to the pyramidal cell arrays following an inside out pattern juxtaposed on concomitant lamination, vascularization, and the introduction of protoplasmic astrocytes (Marin-Padilla 2011). Four excitatory-inhibitory systems have been described in the literature: pyramidal Martinotti, pyramidal basket, pyramidal chandelier, and pyramidal double bouquet cells. The end result of this complex radial glia-mediated migration (pyramidal cells) and coupling to horizontal transversing neuronal precursors (interneurons) is a cortical plate that is a unique mammalian innovation (Gressens and Evrard 1993).

Although minicolumns are readily recognized in fetal/embryonic material, the characteristic radial configuration is less readily ascertained with aging. This may be due to the translation of pyramidal cells around the central axis of the minicolumn, growth or atrophy of anatomical elements, and the introduction of glial elements. At least two studies have looked at the continuity between the ontogenetic minicolumn and its putative postnatal counterpart. Krmpotic-Nemanic et al. (1984) using a limited series of human fetal material from the auditory cortex traced the developmental transformation of ontogenetic cell columns into mature minicolumns. Similar results were observed in a larger series ($n = 67$) of human postmortem specimens that modeled the

rate of change in neuropil space (Casanova et al. 2007). The latter study used Nissl-stained sections and computerized image analysis to measure the median-free path through the neuropil in the radial and tangential directions. No significant change was noted in the ratio of both directions in either the prenatal or postnatal sample population. The maintenance of constant ratios of radial to tangential median neuropil space over the course of development suggests that these morphometric relations reflect an intrinsic organization of circuitry present from the earliest stages of cortical development. Results from the study also suggested that the total cell numbers within a minicolumnar lamina and the corresponding minicolumnar dimensions are constrained by packing limits imposed by their associated vertically oriented processes (Casanova et al. 2007). In effect, corticalization may be determined by the total number of radial units (i.e., radial unit hypothesis of Rakic) only as they ultimately define the total number of minicolumns in the neocortex (Rakic 2003).

Recent studies have given credence to Rakic's radial unit hypothesis (Rakic 1995). It is now commonly accepted that changes in the number of germinal cell divisions giving rise to minicolumns provide for corticalization and brain parcellation (Casanova and Tillquist 2008). Thus, a single microinjection of fibroblast growth factor (FGF) 2 into the cerebral ventricles of rat embryos doubles the number of pyramidal cells while opposite results are noted in a knockout mouse of the *Fgf2* gene (Vaccarino et al. 1999). Similarly, preliminary work on the mouse model for velocardiofacial syndrome suggests that deletion of regulatory genes that control the cell cycle for germinal cells provides for changes in both brain volume and the specification of cells within different cortical layers (Tucker et al. 2008).

Morphometry (Lateralization and Minicolumnar Width)

Comparative neuroanatomy has long studied the existence and meaning of asymmetries in various parts of the human and nonhuman primate brains.

In areas of the human brain associated with language, such as the planum temporale, MRI studies reported essentially identical asymmetries in humans and in African great apes but not in the Old or New World monkey (Gannon et al. 1998; Hopkins et al. 1998). However, an examination of minicolumns between the two hemispheres revealed that minicolumns in homologous regions of the cortex can be lateralized. Perhaps Seldon (1981a) was the first researcher to report an example of minicolumnar asymmetry in his studies of the human auditory cortex. Seldon (1981a) found that cell columns and neuropil space were wider in the left hemisphere as compared to the right. Buxhoeveden et al. (2001) examined cell columns in both hemispheres of humans, chimpanzees (*Pan troglodytes*), and monkeys (*Macaca mulatta*). They reported that minicolumns were lateralized in humans but not in the chimpanzee or monkey brain. The asymmetry consisted of wider cell columns in the left hemisphere. The asymmetrical morphology of cell columns within a brain is highly suggestive of organizational differences between hemispheres (Seldon 1981a, b). Still, despite these interhemispheric differences, gross variability in minicolumnar width appears to be constrained within a brain and within particular species.

In a sample population of autopsy specimens from 67 human patients (*vide supra*; Casanova et al. 2007), five brain regions (areas 4, 17, 21, 22, and 40) were selected to assess minicolumnar width. The width of minicolumns averaged between 40 and 50 μm . The mean minicolumnar width for association cortex (area 40) was 46.8 μm and 31.6 μm for primary visual cortex (area 17). One might conclude that the mean size of minicolumns in human brain falls within a specific range that is generally greater than that of other primates but seemingly equal or smaller than that reported for many other small-brained mammals such as the cat, rabbit, or rat (Buxhoeveden and Casanova 2005; for a review see Casanova 2008a). Comparisons of independent studies in human cortex confirm these numbers (Buldyrev et al. 2000; Del Río and DeFelipe 1997a, b; Seldon 1981a; Schlaug et al. 1995). A study of minicolumns in humans was done by

creating a GLI-profile analysis wherein a linear combination of parameters provided a verticality index (a measure of columnarization) (Schlaug et al. 1995). Regions of the cingulate cortex were examined in normal humans using digitized images of Nissl-stained material. The authors reported a mean minicolumnar spacing of 41.7 μm . Of the five areas examined, area 7 (periculate) displayed the smallest column width of 39.9 μm and area 31 was the largest with 46.6 μm .

Molecular Biology

The genetics underlying neocortical development in autism is complex, reflective of the intricacies of stem cell proliferation, differentiation, migration, neurite outgrowth, and synaptic development. Particular to a significant number of cases of autism is an increase in total minicolumnar number within the neocortex, indicative of an increase of the neural stem cell population (Casanova et al. 2002a). Subject to genetic and epigenetic influences are numerous pathways involved in cell cycle regulation, cellular proliferation, and cell survival. Activation or inhibition of key signaling molecules along these pathways has the potential to upregulate proliferation of the neural germinal population, thereby increasing total minicolumnar number. Targeting of even one or a few molecules can affect activation of related pathways due to crosstalk among them. In addition, upregulation of these pathways may alter migration, neuritogenesis, and synaptogenesis as well because these pathways have been exapted for a variety of forms of growth and development within the cell, linking aberration in cellular proliferation and later minicolumnar morphometry to abnormalities in cell-to-cell connectivity (for review, see Williams and Casanova 2011b). Genetic and epigenetic animal models of autism can illustrate how varying genotypes lead to a common neuroanatomic phenotype. For example, in a subtype of autism spectrum disorders known as Rett syndrome, approximately 80% of cases display a germline mutation of the methyl-CpG-binding protein 2 (*MECP2*) gene on the X chromosome. Due to paternal parent of

origin effects, Rett syndrome mainly targets females. Knockout mice heterozygous for *Mecp2* expression are now used to study the condition at the molecular, neuroanatomical, neurophysiological, and behavioral levels. *MECP2* is a regulatory molecule intimately involved in methylation and deacetylation of DNA within the central nervous system, forming complexes which frequently repress promoter activation. Researchers have found that DNA which is not both methylated and deacetylated remains available for transcription, indicating the vital regulatory position this complex occupies. Even though *MECP2* is ubiquitously transcribed, it exhibits temporal heterogeneous expression in frontal cortex, as *MECP2*^{hi} levels increase with postnatal age and *MECP2*^{lo} levels simultaneously decrease with age (Samaco et al. 2004). This increase in *MECP2*^{hi} levels may help to explain the timing of regressive events seen in Rett syndrome and may offer some insight into regression in idiopathic autism as well. While idiopathic autism rarely presents with *MECP2* mutations, the conditions often exhibit abnormal *MECP2* activation, indicating aberrant regulation upstream of this molecular complex (Samaco et al. 2004).

Another intracellular signaling molecule, phosphatase and tensin homolog (PTEN), is encoded on chromosome 10q23 and regulates cellular growth in part by inhibiting PI3K/Akt pathway activation. While autism is a highly heterogeneous group of conditions with a wide variety of associated mutations, approximately 7% of the autistic population harbors *PTEN* germline mutations (McBride et al. 2010). Within this subpopulation, autism is almost always associated with co-occurring macrocephaly, and in heterozygous *Pten* knockout mice, this macrocephaly is especially apparent. Therefore, given the high rates of *PTEN* mutations within the autistic population, these mice have been proposed as a viable animal model for autism (Kwon et al. 2006).

Tuberous sclerosis is a single gene condition in which 25–50% of those affected also exhibit autistic-like symptoms. The mutations which give rise to the condition target the gene products, tuberous sclerosis complex (TSC) 1 or 2, although

mutations in *TSC2* are more frequently associated with co-occurring autism (Jones et al. 1999). A mutation within either *TSC 1* or *2* can significantly alter its functionality, decreasing inhibition of the mTOR pathway, which is a sensitive detector of growth factors, insulin, and oxidative stress and which also maintains a prime position to either upregulate or downregulate growth based on this incoming information. The resultant phenotype of the condition presents with global or localized forms of megalencephaly, tubers, subependymal nodules, and other proliferative and migratory malformations. Of interest, similar malformations have also been noted within idiopathic autism (Bailey et al. 1998; Wegiel et al. 2010), illustrating how genetic heterogeneity can still lead to a common phenotype.

Recently, the Autism Genome Project Consortium published work comparing 996 autistics to 1,287 matched controls and found significant copy number variations across three functional domains: (1) cellular proliferation, (2) cell projection and motility, and (3) GTPase/Ras signaling (Pinto et al. 2010). While GTPase/Ras signaling may be subsumed under the previous two functions, neuroscientists have had a tendency to view proliferation and projection/motility as distinct cellular processes, and their research have subsequently “split” them by their differences rather than “lump” them by their inherent similarities. But the molecular parsimony which exists between cellular proliferation, neurite outgrowth, synaptic development, and cell movement is considerable. *Molecular parsimony*, otherwise known as the “small toolkit” of molecular biology, suggests that evolution consistently exapts the same types of molecules and signaling pathways to perform new and related functions, such that conserved “families” of genes emerge within and across species. Therefore, the division of a cell into two, the podlike projection of a neuritic arm, the budding of a new synapse, or the slinking movement of a cell along its path have each been refined from a baser process so that they now serve different purposes. And the baser process from which these functions have been borrowed is the general process of growth and division: a common thread tying many, if not all, forms of autism

together. Viewing these conditions in a broader molecular light may help us understand how individuals with such seemingly disparate genetic backgrounds, and arising from complex ecologies, can each be at risk for the development of autism.

Minicolumnar Networks: Electrophysiology and Circuitry

The minicolumn is defined by cytoarchitectural arrangements of cell elements aligned with the core of pyramidal cells and the apical dendrite and myelinated axon bundles arising from them. Apical dendrite bundles and myelinated axon bundles vary in number and laminar origin and cell type of their constituents, according to species and area. They are spaced in register with pyramidal cell columns and interneurons; the distribution and structure of these constituents provide complementary parameters for morphometric analysis. The basis for the computational flexibility of microcircuit functions in the minicolumn lies in the regulation of the core pyramidal cells’ electrotonic properties by interneuron class-specific networks and their synaptic distributions in the various membrane compartments of pyramidal cells. Coordinated inhibition on proximal dendritic segments results in the functional segregation of the soma and distal dendrite compartments. Tonic inhibition applied to basal dendrites or proximal to the apical dendrite tuft in layers I and II disrupts excitatory postsynaptic potentials (EPSPs) arising from cells in neighboring minicolumns and limits their input. Moreover, the disposition of interneuron connections modulates activity in the recurrent pyramidal cell circuits whose positive feedback properties render them unstable. Interneuron regulation of the reverberant properties and gain of these circuits allow for the maintenance of information in each minicolumnar circuit in a metastable state. In this way, a signal input could allow for the mutual relaxation of minicolumn subsets into a stable state, providing a basis for pattern completion or matching. Thus, each subclass of interneuron plays critical functional roles in control of trans-laminar circuits.

In the canonical cortical microcircuit proposed by Douglas and Martin (2004), the flow of excitatory information from upstream areas or thalamocortical inputs is directed toward middle layers. As was noted earlier, most circuits in cortex are recurrent and local. In cat visual cortex, thalamocortical synapses were calculated to constitute less than 7% of the total number of inputs to layer IVc spiny stellate cells (Ahmed et al. 1994). While sparse, this input is highly divergent and convergent both on other spiny stellate stars and on target pyramidal neurons in layer II/III (Lübke et al. 2000, 2003). Thalamocortical inputs also provide direct input to GABA neurons, primarily parvalbumin-expressing (PV+) basket cells or vasoactive intestinal peptide (VIP+) bipolar cells (Freund et al. 1985; Hájos et al. 1997; Staiger et al. 1996, 1997). Subpopulations of spiny pyramidal and stellate neurons in layer IV form precise retinotopic patterns in primary visual cortex (VI) of cats and rodents (Burkhalter 1989; Parnavelas et al. 1977). What is notable is that these precise patterns of inputs feed ordered arrangements of fine-scale microcircuits. Double cell intracellular recordings of pyramidal cell pairs in layer II/III (Yoshimura et al. 2005) revealed that pyramidal cell pairs which received common afferents were significantly more likely to be reciprocally connected. This specificity was also established for connections between fast-spiking interneurons and pyramidal neurons, with fast-spiking interneurons preferentially forming reciprocal rather than one-way connections with pyramidal cells, providing a dedicated feedback circuit (Yoshimura and Callaway 2005). In addition, these interneurons only received input from pyramidal neurons which were already interconnected or from strong layer 4 afferents. Fast-spiking interneurons were dedicated to fine-scale pyramidal cell circuits, thereby providing a strong source of feature-tuned feed-forward inhibition to these circuits (Yoshimura and Callaway).

The brain's limited long-range wiring cannot directly sustain coordinated activity across arbitrary cortical locations, but it can convey *patterns* of synchronous activity as oscillatory neuronal fluxes, represented by local field potentials measured by electroencephalography (EEG).

Coordination of oscillations at varying interacting frequencies allows for relatively efficient and unconstrained segregation or integration of cognitive representations in varying forms and across hierarchical levels. Disrupted patterns of coordinated oscillatory output in distributed minicolumnar networks might be associated with cortical disconnection in autism. Likewise, altered oscillatory activity in developing cortical circuits may contribute to impaired development of intra-areal and transcortical connections (Casanova and Trippe 2009).

Minicolumnar Networks: Neurochemistry

Oscillations of pyramidal cells in minicolumns and across assemblies of minicolumns are maintained by networks of different species of inhibitory, GABA-expressing, interneurons. GABA neurons are classified according to characteristic combinations of morphological, physiological, or molecular phenotypes (Ascoli 2008). Cell morphologies are conventionally classified as basket cells (interneurons having a large proportion of terminals on soma or proximal dendrites), chandelier cells (defined by vertical arrays of cartridge terminals aligned on pyramidal cell initial segments), and double bouquet cells (interneurons having predominantly radially aligned axodendritic arbors). Most interneurons express only one of the calcium-binding proteins parvalbumin or calretinin, or the neuropeptide somatostatin but not the others. Radially oriented interneurons containing calretinin commonly coexpress vasoactive intestinal peptide (VIP). Basket cells and chandelier cells containing parvalbumin have a fast-spiking synaptic dynamics with high amplitude. Other basket cells containing the neuropeptide cholecystokinin, and never parvalbumin, have irregular-spiking profiles. Radially oriented cells typically have an accommodating broader synaptic profile which varies according to cell type and connections. While tangentially arrayed basket cells function, in part, to coordinate activity among remote neuronal ensembles, by contrast, radially oriented

inhibitory interneurons prominently located in the peripheral neuropil space surrounding pyramidal cell columns likely function to segregate columns from interference, both from other minicolumns within an array and from fields of activity or inhibition in neighboring minicolumnar arrays.

Cholinergic inputs to cells of either cholecystokinin (CCK+) or PV + basket cell subclasses are complementary and nonoverlapping (Fig. 1). Cholinergic activation of alpha-7 subunit-containing nicotinic receptor expressed in CCK + basket cells results in depolarization and increased GABAergic output. In rodent hippocampus, CCK + cell depolarization profiles vary according to interneuron size or molecular features (Kawaguchi 1997). By contrast, PV + interneurons express presynaptic muscarinic M₂ receptors (Hajos et al. 1998) which serve to inhibit GABA release from PV + basket cell and GABAergic drive on pyramidal neurons. Given acetylcholine's well-established role in refining neuronal circuits and in increasing attention and perceptual feature selectivity (Hajos et al. 1998;

Kawaguchi 1997), this complementary expression pattern suggests a mechanism whereby increased presynaptic activation of CCK + interneurons and modulation of their gamma-band activity facilitates dynamic restructuring of connections between established networks in response to environmental or state-dependent cholinergic inputs; "clocklike" (Freund 2003) oscillatory drive of PV + neurons is suspended, and long-term plasticity of these interneuron networks will depend on the circuit remodeling driven by CCK + cells. Disruptions of the dynamic GABAergic balance synergistically regulated by cholinergic pathways, endocannabinoids, monoamines, and other neuroactive molecules would therefore affect the integration of local microcircuits into wider networks, a pathogenetic trajectory consistent with our current understanding of the behavioral pathology of autism as a "disconnection syndrome" (Casanova et al. 2006a; Just et al. 2004).

CCK + basket cells are notable for the restricted axodendritic arbor field to within

Neural Mechanisms in Autism, Fig. 1 Role of CCK cells within minicolumnar cell architecture (see text for explanation). *Circles* represent interneurons, *triangles* represent pyramidal cells. Abbreviations: cholecystokinin (CCK), calretinin (CR), parvalbumin (PV), and somatostatin (SST) *Right:* laminae; *dotted, vertical lines:* minicolumnar boundaries

minicolumnar dimensions, together with radial interneurons expressing varying combinations of calretinin (CR), calbindin (CB), VIP, or somatostatin (SOM). As recently shown in monkey prefrontal cortex (Zaitsev et al. 2009), some CR + radial interneurons extending across most cortical layers or into white matter give rise to perisomatic baskets in superficial layers which surround small cell profiles resembling interneurons. Moreover, CBR1 mRNA and protein expression are distributed along a vertical translaminal gradient, with mRNA expression most intense in superficial layer II and CBR1 immunoreactivity increasing to a maximum in deep layer III (Eggan and Lewis 2007; Zaitsev et al. 2009). One implication of this finding is that CBR1/CCK + basket cell terminals may have a vertical distribution extending from their cell body. Radially oriented interneurons may therefore serve to coordinate activity of CCK + basket cells across layers of a minicolumn thereby regulating development of its recurrent circuits during development. CCK + interneuron circuits are more susceptible to disruption than are PV + interneurons and that disruption has greater pathological impact (Freund 2003). This may indicate that they, along with CR + or VIP + radial interneurons, serve as “keystones” in interneuronal networks driving synchronous interneuron activity across supra- and infragranular layers of a minicolumn.

Minicolumnopathy of Autism

Recent postmortem studies have found area-specific alterations in minicolumnarity. All of these studies have been carried out targeting pyramidal cell arrays in Nissl stains as immunocytochemical markers may prove unreliable given the long postmortem intervals before autopsy and the variability in agonal conditions between patients and normative individuals. The first study was provided by Casanova et al. (2002a) using celloidin-embedded Nissl material from nine autistic patients and an equal number of controls. Three brain areas (9, 21, and 22) were studied. In this study, the brains of autistic individuals were found to have smaller minicolumns ($p = 0.034$)

with most of the decrease attributable to a reduction in the peripheral neuropil space. Results were later on validated when the same series was analyzed according to the gray level index (GLI) (Casanova et al. 2002b).

A more recent study used an independent sample to analyze minicolumnarity within representative primary sensory, motor, and prefrontal association cortices (areas 17, S1, 4, and 9) (Casanova et al. 2006a). Differences in tissue preparation and section thickness prevented direct comparisons with earlier studies. However, minicolumnar width was significantly diminished in autistic individuals as compared to controls ($p = 0.023$) (Fig. 2). The finding was also corroborated by using GLI measures of distance between amplitude peaks. Nucleolar area was thresholded from the background and found to be smaller in autistic individuals. A Boolean model found greater density of Nissl-stained elements (neurons). A Delaunay triangulation method suggested a diminution in the distance between minicolumns but an otherwise normal complement of neurons within minicolumns. The authors concluded that the decrease in neuronal and nucleolar size noted in autistic subjects could constrain the length of corticocortical projections thereby biasing their circuitry toward shorter connections (arcuate fibers) at the expense of longer ones (i.e., commissural projections) (Casanova et al.).

A study of minicolumnar abnormalities in postmortem samples of brains of autistic individuals and controls was expanded on previous findings by exploring nine cortical areas that included paralimbic, heteromodal association, unimodal association, and primary or idiopathic areas (Casanova et al. 2006b). Computerized image analysis clustered neurons into minicolumnar fragments. The authors found an interaction of diagnosis and region for neuropil space ($p = 0.041$). Post hoc analysis showed significant differences for the frontopolar region (area 10) and the anterior cingulate gyrus (area 24). The smaller minicolumns in autism translate into more of them per unit of length. The assumption of an increase total number of minicolumns was modeled to true columnar parameters (three dimensions) with a strong correlation (Casanova and Switala 2005).

Neural Mechanisms in Autism,

Fig. 2 Minicolumns in a section of primary motor cortex (Brodmann area 4), lamina III, in an autistic patient (*bottom*) and an age-matched control case (*top*). *Insets* highlight the cores of minicolumn fragments. Scale bars measure 200 μm on *left* and 50 μm on *right*

Estimates of cortical interconnectivity suggest that each module (minicolumn) is connected to 10^3 other modules (Casanova 2004). If connectivity is fixed as brain size increases, the number of connections would scale as the number of modular units squared. Most of the addition in white matter takes the form of short corticocortical fibers as longer connections incur a penalty of increased conduction time and metabolic demands. Not surprisingly, MRI studies parcellating the white matter have found a disproportionate increase in the outer white matter compartment (short late myelinating fibers) as opposed to inner compartment containing longer bridging connections (Herbert et al. 2004).

Future Directions

Genome-wide linkage screen have refuted the concept of autism as having a Mendelian inheritance and rather sustain the condition as a multifactorial disorder. The author has proposed a “triple hit hypothesis” where manifestations supervene whenever three factors converge on a particular infant: (a) a critical period of brain development, (b) an underlying genetic vulnerability, and (c) exogenous stressor(s) (Casanova 2008b) (Fig. 3). While it is important to investigate the genetics of autism, it is also important to remain aware that phenotype is a combination of genetic and epigenetic influences. And therefore, environmental agents which target pathways

Neural Mechanisms in

Autism, Fig. 3 Autism is a multifactorial disorder where manifestations supervene when three factors impinge to various degrees upon a particular infant: (1) a critical period of brain development, (2) an underlying vulnerability (genetics), and (3) exogenous stressors (Casanova 2008a)

common to autism may lead to comparable phenotype yet not be reflected within the genotype. A variety of teratogenic agents have already been associated with the conditions, and more epigenetic influences will likely come to light with further research (Williams and Casanova 2011a). The overriding theme of autism is that overactivation of key growth-related pathways during vulnerable time periods of development may lead to the conditions (Levitt and Campbell 2009; Williams and Casanova 2011a).

The value of understanding the putative minicolumnopathy of autism lies in its explanatory powers and translational possibilities. Early results predicted changes in brain volume, alterations in the ratio of gray to white matter, bias in white matter parcellation (inner vs. outer white matter), and abnormalities in gamma-binding frequencies (Casanova et al. 2002c). More recently, the idea that autistic individuals have defects in their minicolumnar peripheral neuropil space has provided for a possible clinical intervention using rTMS to strengthen the inhibitory surround of

these modules (Sokhadze et al. 2009a, b, c). Other therapeutic attempts based on the minicolumnopathy of autism include the shifting of the terminal fields of sensory stimuli as a way of compensating for the bias in short connections observed in this condition.

Definition

Circuitry Implicated in the Cognitive Control of Emotion

Emotion regulation refers broadly to the implementation of automatic or intentional strategies to modulate the trajectory of an emotion or emotional state in order to promote adaptive, goal-directed behavior. Further, the use of functional MRI (fMRI) has provided insight into the neural systems of cognitive control that support regulatory strategies and the modulation of emotional reactivity. Examples of cognitive-based strategies that are amenable to functional imaging paradigms of cognitive control include attentional deployment, which involves controlling the gating of emotional stimuli (e.g., selective attention, distraction); response modulation, which involves strategies to modulate expression of negative emotions (e.g., suppression); and cognitive change, which involves altering the interpretation or meaning of a stimulus (e.g., reappraisal).

Several cognitive processes and neural systems are involved in regulating emotions. In particular, prefrontal regulatory regions including the ventromedial and ventrolateral prefrontal cortices (PFC), ventral anterior cingulate cortex, dorsolateral prefrontal, and parietal regions are primarily involved in modulating the emotional reactivity of regions such as the amygdala, insula, ventral striatum, and periaqueductal gray (Dolcos and McCarthy 2006; Etkin et al. 2015). For instance, the ventromedial PFC, a key region implicated in emotion regulation, downregulates amygdala reactivity in response to threat and other negative stimuli (Ochsner et al. 2012; Silvers et al. 2016). Thus, intact emotion regulation (e.g., cognitive reappraisal) can be characterized by the activation of regions involved in emotional reactivity in response to aversive or negative stimuli, such as threat and fear, and this response is then dampened by ventral prefrontal regions involved in the cognitive control of emotion (Ochsner et al. 2012).

Neural Bases of Emotion Dysregulation in ASD

Deficits in emotion regulation are postulated as a mechanism underlying several psychiatric disorders including internalizing disorders (Jazaieri et al. 2015), disruptive behavior disorders, and autism spectrum disorder (ASD) (Mazefsky et al. 2014). On a neural-systems level, models of emotion dysregulation implicate perturbations in functional connectivity, a measure of the synchronization in activity in between two brain regions, between the amygdala and ventral prefrontal cortex (vPFC) as a possible shared underlying mechanism across several psychiatric disorders characterized by impairments in cognitive control (Etkin et al. 2015; Ochsner et al. 2012). For instance, hyperactive circuitry of emotional reactivity, such as the amygdala, paired with reduced vPFC response to emotional stimuli is associated with anxiety disorders (Goldin et al. 2013), disruptive behavior disorders (Coccaro et al. 2011), and ASD particularly in the presence of co-occurring disorders including anxiety (Herrington et al. 2017) and disruptive behaviors (Ibrahim et al. 2019).

Emotion dysregulation in ASD may be characterized by reduced functional connectivity

between the amygdala and vPFC during emotional perception and cognitive control tasks. For instance, decreased connectivity between the amygdala and ventrolateral PFC was shown during cognitive reappraisal in response to disgust-inducing images in children with ASD (Pitskel et al. 2014). Similarly, reduced prefrontal response during cognitive reappraisal was also shown in adults with ASD, suggesting a shared mechanism of emotion dysregulation among children as well as adults with ASD (Richey et al. 2015). Recent work also implicates differential patterns of reduced connectivity between the amygdala and ventrolateral PFC in children with ASD and co-occurring disruptive behavior in comparison to children with ASD without disruptive behavior (Ibrahim et al. 2019). Similar to findings from fMRI studies in non-ASD youths with conduct problems (Lozier et al. 2014), distinct relationships between callous-unemotional traits and severity of disruptive behaviors with amygdala reactivity have been shown in children with ASD. In particular, greater levels of callous-unemotional traits were found to be related to reduced amygdala reactivity, while the opposite pattern of greater levels of disruptive behavior was found to be related to increased amygdala reactivity to emotional faces (e.g., fearful) in children with ASD when controlling for the variance of the other variable (Ibrahim et al. 2019). Thus, it is possible that emotion dysregulation in ASD, particularly in the presence of co-occurring disorders, could be associated with connectivity patterns that are shared across children without ASD neural systems.

Given that face processing impairments are common in ASD, it is also important to note that perturbed responses in cognitive control circuitry, particularly the amygdala and vPFC circuit, have been shown during social perception including emotion processing tasks such as viewing emotionally expressive faces (Davies et al. 2011; Swartz et al. 2013) and social cognitive tasks such as viewing biological motion (Di Martino et al. 2009). Therefore, it is possible that aberrant recruitment of emotional reactivity and control circuitry during social perception could indicate misinterpretation or reduced

saliency of social cues in individuals with ASD. Conversely, amygdala hyper-reactivity as well as amygdala-vPFC hyper-connectivity was also shown in individuals with ASD during face perception tasks (Kleinhans et al. 2011; Monk et al. 2010; Tottenham et al. 2013), which could indicate heightened sensitivity to threat or lack of differentiation of threat versus safe social cues (Top et al. 2016).

In terms of future work, it is not clear which neural components underlying emotion regulation are most affected in ASD in the presence of a co-occurring disorders when different cognitive control processes are engaged (e.g., reappraisal vs. suppression vs. selective attention). Likewise, more work is needed to elucidate whether emotion regulatory impairments in ASD are due to a failure to activate specific cognitive control regions or abnormalities in the synchronization or connectivity between large-scale networks. Few studies have also examined the neural response to multiple sensory stimuli in ASD based on an emotion regulation framework (Green et al. 2015). Given that sensory over-responsivity including severe negative responses to stimuli (e.g., sounds, noisy environments, textures) is prevalent among youths with ASD, future studies are needed to understand possible dysfunction in emotion regulation circuitry during exposure to sensory stimuli. Further, the use of a dimensional approach to model cognitive control along a continuum in ASD, as well as in comparison to other clinical comparison groups, could reveal new insights into the relationship between emotion regulation circuitry and severity of associated symptoms, supporting the identification of possible neuroendophenotypes that could serve as mechanism-based targets for personalized treatments in ASD.

Definition

As a field, clinical research is increasingly moving toward the goal of precision medicine (Insel 2014), an initiative that highlights the importance of taking into consideration individual differences from the genetic to behavioral level when formulating effective treatment plans. Recent advancements have increasingly adopted an interdisciplinary approach to overcome two major barriers: (1) to better characterize *how* a treatment can elicit change at the *individual* level, and (2) to predict *who* will most likely respond to the intervention. Successful integration of neuroimaging techniques and behavioral measures have the potential to guide identification of sensitive and objective biomarkers that can reflect and predict response to specific evidence-based treatment models in individuals with autism spectrum disorder (ASD). By integrating knowledge from social and cognitive neuroscience that have shown atypical neural response among individuals with ASD when processing social stimuli compared to typically developing (TD) individuals (Adolphs 2009), as well as established neural signatures of ASD (Kaiser et al. 2010), neuroimaging techniques can facilitate the progression toward precision medicine in two ways.

First, clinical research relying on behavioral measures alone are not sufficient for overcoming the challenge of equifinality, where similar behavioral gains observed across participants following treatment might mask differential underlying mechanisms of change. Integrating neuroimaging techniques such as functional magnetic resonance imaging (fMRI) can help characterize the heterogeneous neural mechanisms of change underlying similar behavioral gains observed across participants. fMRI examines functional changes in brain response to social stimuli that are both common at the group pathology level of ASD, and unique changes at the individual level (Venkataraman et al. 2016; Ventola et al. 2015). Therefore, the utilization of neuroimaging tools can help clinicians to better understand not only *how* a treatment can elicit change, but also how change is occurring at the *individual* level, which can inform future treatment decisions. Second, tracking clinically sensitive biomarkers can enable clinicians to both objectively quantify and qualitatively assess trajectories of change over the course of treatment (Ventola et al. 2015; Voos et al. 2012), and data collected over time can help generate predictive models of responder profiles to treatment (Yang et al. 2016), assisting the understanding of *who* will most likely respond to intervention.

One evidence-based intervention that has seen a recent expansion in identifying neural signatures of treatment response is pivotal response treatment (PRT), a behavioral-based intervention primarily aimed to target social communication skills in children with ASD (Koegel et al. 1987; Koegel and Egel 1979; Koegel and Koegel 2012; Verschuur et al. 2013). Based on principles of applied behavior analysis (ABA), PRT adopts a more naturalistic approach and employs a variety of strategies to increase children's motivation, such as following the child's choice, interspersing maintenance and acquisition tasks, and reinforcing both correct responses and appropriate attempts to increase the frequency of children's exposure to naturally contingent reinforcements (Koegel et al. 1987; Koegel and Egel 1979). Building upon its large empirical evidence base from behavioral studies (Verschuur et al.

2013), recent advancements have begun to integrate neuroimaging techniques to identify both neural signatures of treatment response (Ventola et al. 2015; Voos et al. 2012), as well as neural biomarkers to help predict responder profiles to PRT (Yang et al. 2016).

This entry will first outline the current state of science behind the identification of brain areas of interest to serve as potential neural signatures of treatment response in individuals with ASD, as well as the evidence supporting the use of functional paradigms sensitive to detect clinically meaningful outcomes in terms of neural response to social stimuli. Next, a critical evaluation of recent advancements in identifying neural signatures of treatment response to PRT for individuals with ASD is offered. Finally, future directions for expanding research to help uncover neural signatures of treatment response can increase the use of other noninvasive and more cost-effective techniques such as electroencephalography (EEG), as well as eye-tracking are discussed, alongside limitations to take into consideration for future research.

Background: Examining the Current State of Science

Overview of Neural Signatures of ASD

Recent advancements in the identification of neural signatures of treatment response for individuals with ASD have relied on the assimilation of knowledge from social and cognitive neuroscience research, to first establish a robust profile of neural correlates that can reliably detect differences in social cognition among individuals with ASD compared to their TD peers. One well-established paradigm known to reliably elicit differential patterns of neural response in brain regions associated with social cognition among individuals with and without ASD is a biological motion paradigm (Klin et al. 2009; Pavlova 2012; Pelphrey et al. 2003), which depicts a series of either biologically coherent (BIO) or scrambled (SCR) motion by using a series of point-light displays (Fig. Fig. 1). For the biologically coherent displays, the point-light displays depict social

Neural Signatures of Treatment Response, Fig. 1 Stimuli showing biological and scrambled motion paradigm

movements such as a person dancing, walking, or playing games that are familiar to children such as pat-a-cake (Pelphrey et al. 2003). The ability to perceive form from biological motion capitalizes on the intrinsic visual sensitivity toward kinematics that is congruent with the spatiotemporal dynamics of movements elicited by biological agents (Johansson 1973; Pavlova 2012; Puce and Perrett 2003).

Biological motion paradigms have been widely used in both primate and human neuroimaging research to study social cognition, and have generated convergent findings that highlight the role of superior temporal sulcus (STS) in the recognition of socially salient information (Oram and Perrett 1994, 1996; Puce and Perrett 2003; Vaina et al. 2001). Primate findings have shown that sensory integration occurs when motion-related information from the dorsal pathway and form-related information from the ventral pathway derived from the same biological object

converge at the superior temporal polysensory area (STP; found within the STS) within 100 ms, enabling perception of coherent biological motion (Oram and Perrett 1994, 1996). In humans, similar response profiles are seen in typically developing adults, where biological motion have been shown to activate both the ventral and dorsal visual pathways as well as the point of confluence at the superior temporal gyrus (STG), the homologue region to the STP found in primates (Pelphrey et al. 2003; Vaina et al. 2001), as well as the fusiform gyrus (FG) known for facial recognition. In TDs, preferential looking toward biologically coherent motion emerges during early infancy, and serves to bias one's attention toward socially salient stimuli (Klin et al. 2009), which is an important behavioral precursor to later-emerging social cognition and affect regulation skills (Baron-Cohen 1997; Frith and Frith 1999). This is further supported by neurobiological findings, where STS projects to both the amygdala and orbitofrontal cortex (OFC) which are involved in processing emotionally salient information and affect regulation, and together form part of the social cognition network associated with theory of mind (Adolphs 2009; Baron-Cohen 1997; Brothers 2001). Therefore, biological motion is a well-validated paradigm that is known to elicit robust response profiles in brain areas involved in social information processing, and atypical profiles of neural response to BIO versus SCR motion may be indicative of pathology that impacts social cognitive processing (Kaiser et al. 2010; Ventola et al. 2015; Voos et al. 2012).

To better characterize the distinct neural profile associated with ASD that might underlie differences in social cognition when compared to TD peers, Kaiser et al. (2010) compared and contrasted the neural response to BIO versus SCR motion in children with ASD ($n = 25$) with their unaffected siblings (US; $n = 20$) and TD children ($n = 17$). The authors conducted whole-brain analysis at voxel-wise uncorrected threshold level of $p < 0.05$, to evaluate brain regions that showed increased activation during BIO versus SCR motion (BIO>SCR) in TD>SD, TD>US, US>ASD, and US>TD group comparisons. To ensure that the false positive discovery rate of

active voxels is $<5\%$, only clusters that exceeded a cluster threshold of >20 contiguous voxels at $\alpha < 0.05$ within each group level comparison were selected. The further determine α value for each cluster, the relative occurrence of each cluster during 5000 iterations of Monte Carlo simulation was noted. In order to determine distinct neural profiles of (a) "state," (b) "trait," and (c) "compensatory" patterns of activation in response to biological motion, higher-level conjunction analyses were conducted using an uncorrected voxel-wise threshold level of $p < 0.0025$, and a cluster threshold of $k > 20$ to further control for the rate of false positives (Fig. 2).

The "state," "trait," and "compensatory" regions served as unique neural signatures that characterized the differential response to biological motion across ASD, US, and TD children. "State" regions refer to brain areas that showed reduced activation during BIO>SCR in children with ASD only, thus indicative of atypical neural response to social stimuli unique to the state of ASD pathology. Such regions included ventromedial and left ventrolateral prefrontal cortex (vmPFC; vlPFC), right amygdala (rAMG), bilateral fusiform gyrus (FG), and right posterior superior temporal sulcus (rpSTS). "Trait" regions refer to brain areas that showed reduced activation during BIO>SCR in both children with ASD and US relative to TD children, thus indicative of an endophenotype underlying atypical neural response to social stimuli that may be associated with shared genetic vulnerability between ASD and TD. Such regions included right inferior temporal gyrus (ITG), left dorsolateral prefrontal cortex (dlPFC), and anterior bilateral fusiform gyri (FG). "Compensatory" regions refer to differential neural response to BIO>SCR found in US group only, suggesting possible compensatory effects to overcome their shared vulnerability with the ASD group that affects their ability to process social stimuli. Such regions included anterior rostral vmPFC and caudal rpSTS. Taken together, the "state," "trait," and "compensatory" profiles guide the selection of sensitive biomarkers that can detect atypical brain response to social stimuli both specifically related to ASD pathology, and

those that are related to the broader autism phenotype, providing a more comprehensive overview of the range of phenotypic abnormalities associated with disrupted social information processing related to ASD.

Evaluating Sensitivity of Neural Signatures of ASD as Clinical Biomarkers

Building upon the empirical data that have characterized biomarkers indicative of atypical response to social stimuli among children with ASD (Kaiser et al. 2010), such biomarkers may be clinically informative when monitored over the course treatment to help objectively quantify both the quality and magnitude of change in brain responsiveness to social stimuli. Furthermore, the demarcation of whether changes occur in areas that correspond to “state” or “compensatory” neural profiles can inform clinicians if following treatment, children with ASD may show increased normalization of brain response to social stimuli within the BIO>SCR contrast compared to TD children (by increased activation in “state” and “trait” regions), or if there are compensatory effects analogous to that observed in their unaffected siblings (by increased activation in “compensatory” regions), or both.

To assess the clinical sensitivity of the identified neural signatures as potential biomarkers of treatment response, Voos et al. (2012) conducted the first fMRI study (case study) to evaluate whether behavioral changes in increased social functioning following 16 weeks of PRT is accompanied by simultaneous increased brain activation to biological motion in two high-functioning children with ASD. Primarily targeting social communication skills in children with ASD, PRT embeds learning opportunities naturally within games that are intrinsically motivating to each child, and delivers natural reinforcements contingent upon each child’s appropriate social attempts and responses to increase social initiations, use of functional language, and overall social reciprocity (Koegel et al. 1998; Koegel et al. 1987; Koegel and Egel 1979). Individualized treatment goals were established for each participant at the onset of treatment, which included lower-level social skills such as appropriate body positioning and voice modulation for participant one, and higher-

level social skills such as social reciprocity, perspective taking, and use of functional language to initiate and make requests for participant two. Following PRT, clinical assessments by using the Autism Diagnostic Observation Schedule (ADOS) and Clinical Evaluation of Language Fundamentals (CELF-4) showed significant improvements in social functioning and use of adaptive language for both children. In response to biological motion, significant increases in activation were only observed in “state” and “trait” regions, where both children showed gains in bilateral FG. In addition, participant two showed more widespread collateral gains in other “state” areas including rpSTS and vIPFC, reflective of higher-order social processing skills targeted during PRT. The overlapping, yet distinct neural profiles of change across both participants, is important to note, as it helped to partition differential mechanisms of change underlying similar behavioral gains assessed by clinical measures, and helps to overcome the problem of equifinality by noting how treatment response might differ at the *individual* level.

The use of fMRI also helped to elucidate the mechanism underlying *how* PRT may be inducing social gains in children with ASD, as the lack of change in activation of “compensatory” regions highlights that PRT elicited social gains in both children were driven by an increased normalization of neural response to social stimuli that is more comparable to the developmental trajectory of their TD peers. However, there are several limitations in Voos et al. (2012)’s findings. First, it was a case study with two participants so not generalizable to the wider clinical population. Second, no control groups were included, thus making it challenging to conclude whether the changes in brain activation to BIO>SCR were specific to PRT per se, or reflective of broader developmental changes that naturally occurred over the course of 16 weeks for both participants. Nonetheless, the Voos et al. (2012) study is important to note as it showed that the neural signatures of ASD identified by Kaiser et al. (2010) can potentially serve as clinically sensitive biomarkers that can track changes in social functioning at the brain level, within the timeframe of 16 weeks of PRT for children with ASD.

Current Knowledge: Neural Signatures of Pivotal Response Treatment

Overcoming the Challenge of Equifinality

Based on exploratory results from Voos et al. (2012) that demonstrated the clinical sensitivity of neural signatures of ASD in detecting change in social functioning at the brain level in individuals with ASD, it is important to further examine how individual variances in neural profiles presented at baseline might further influence the trajectories of functional changes observed over the course of PRT. Identifying changes in functional neural pathways might indicate possible heterogeneous mechanisms of biological change underlying behavioral gains in social functioning observed in children with ASD, and help to address not only *how* a treatment might be eliciting positive social outcomes, but also how such outcomes are occurring at the *individual* level.

To capture heterogeneity that might underlie similar behavioral manifestations of reduced social responsiveness such as inattention to faces and poor eye contact in children with ASD, Ventola et al. (2015) examined the brain response profile to BIO>SCR in the rpSTS in ten high-functioning children with ASD compared to five TD children. Relative to the mean activation level in rpSTS at the group level to biological motion at baseline found in TD children, five children with ASD demonstrated relatively hyperactive rpSTS activation (ASD>TD), and five children demonstrated relatively hypoactive rpSTS activation (TD>ASD). The authors hypothesized that the hyper- and hypoactive groups at baseline might experience different challenges that disrupted their response to social stimuli at baseline. Specifically, the hyperactive group might experience reduced sensory gating and poor attentional control, resulting in hyperarousal when exposed to socially salient information at baseline (Markram and Markram 2010), and reflected by increased activation of thalamus, amygdala, and temporal cortical regions. In comparison, the hypoactive group might experience reduced social motivation when attending to social stimuli, reflected by reduced activation in reward processing regions such as the ventral striatum (VS), nucleus accumbens (NAcc), and amygdala (Chevallier et al. 2012).

Following 16 weeks of PRT, both hyper- and hypoactive groups showed significant improvements in social functioning assessed by behavioral measures, though distinct patterns of underlying neural mechanisms of change emerged. For the hyperactive group, the authors found reduced activation in rpSTS and other brain areas related to sensory gating and attention control (thalamus, amygdala, and hippocampus) during biological motion, suggesting improvements in regulating sensory gating and arousal levels in response to social stimuli following PRT. For the hypoactive group, the authors found increased activation and functional connectivity between both the rpSTS and the VS, a major region involved in reward processing, as well as other regions of the mirror neuron system (Fig. 2), suggesting improvements in social reward processing. Therefore, Ventola et al. (2015) successfully showed that not only does PRT elicit normalized neural response profiles to socially meaningful stimuli that accompanies behavioral social gains in children with ASD, but that changes occur differentially at the individual level, suggesting each child with ASD may be benefitting from PRT in individualized ways. Unmasking the heterogeneous neural mechanisms of change underlying similar behavioral gains can help clinicians to better identify how different active ingredients of PRT may be elicit therapeutic potentials for each child with ASD, and help to develop more individualized goals matched with appropriate intervention techniques to more effectively address each individual's social deficits, thus moving toward the goal of precision medicine.

Finally, given that functional changes in response to social stimuli can be seen at the regional level following PRT, it is interesting to conjecture whether co-occurring changes in functional connectivity between brain regions involved in lower- and higher-order social information processing may be altered at the brain circuitry level. This is of particular interest given that PRT simultaneously targets many social skills ranging from lower-level skills, such as increasing frequency of social initiations, to higher-level perspective-taking and self-monitoring. Investigating how such co-occurring behavioral social gains may elicit functional

rewiring of the brain in response to social stimuli can further examine whether PRT may be beneficial in increasing the brain's overall efficiency at processing meaningful social information. In a sample of 19 high-functioning school-aged children with ASD, Venkataraman et al. (2016) evaluated co-occurring regions that showed changes in functional connectivity that accompanied aggregated functional change in response to biological motion in the posterior cingulate cortex (PCC) following 16 weeks of PRT. The authors found notable changes in brain circuitry associated with processing and assignment of reward values to external stimuli implicated by reduced functional connectivity to orbitofrontal cortex (OFC), as well as circuitry associated with facial recognition implicated by increased functional connectivity to occipital-temporal cortex. Taken together, PRT is shown to elicit both normalized trajectories of brain response to social stimuli both at the regional and brain circuitry level, suggesting there may be improved neural efficiency in processing socially salient information in children with ASD.

Predictors of Responder Profile

In addition to addressing *how* treatment may elicit change at the individual level, incorporating neuroimaging tools can also help to characterize neural profiles that might *predict*, at baseline, an individual's response to treatment. Identifying neural predictors of treatment response can guide clinicians to select more appropriate treatments for individuals with ASD, and to maximize the cost and time efficacy for eliciting positive therapeutic gains. Furthermore, identifying neural predictors of treatment response and the corresponding behavioral profiles can increase clinicians' awareness of areas that may be more treatment resistant, and require greater care when formulating treatment plans to develop effective strategies targeting such areas without breaching fidelity of treatment protocol. From a neuroimaging perspective, it is possible to conduct a retrospective regression analysis to assess how brain activation in response to social stimuli at baseline might predict the magnitude of improvement in social functioning following treatment, thus identifying possible neural predictors of treatment response.

Monitoring changes in brain response to biological motion, Yang et al. (2016) conducted regression-based multivariate pattern analyses (MVPA) to decode how unique distributions of voxel activation pattern at baseline within neural networks can be associated with the efficiency of social cognitive processing. The authors found that response to BIO>SCR in four neural clusters at baseline subsequently predicted the magnitude of increase in social competency following 16 weeks of PRT in 20 children with ASD, which included areas such as the STS, superior parietal lobule, FG, vmPFC, VS, and putamen. Functionally, the identified brain areas corresponded to a range of social and cognitive functions including motion and object recognition, emotion regulation and response inhibition, visuospatial attention, and reward processing. Furthermore, the authors utilized a cross-validation design and found that the MVPA model of pretreatment response trained using one cohort of patient data was able to successfully predict changes in social functioning in a second independent cohort of patient data, suggesting that neural predictors identified may be generalizable across children with ASD. However, treatment specificity to PRT of the biomarkers identified could not be assessed, as the authors did not include an alternative treatment group for comparison, which warrants further attention. Despite the limitation, the successful implementation of MVPA by integrating fMRI and behavioral data has shown a promising first step for moving toward the goal of identifying *who* will most likely benefit from PRT among children with ASD, a major obstacle en route to establishing precision medicine in psychiatry.

Implications and Future Directions

In summary, research evaluating neural signatures of treatment response has many valuable clinical implications. Characterizing neural signatures that can both objectively quantify and show qualitative differences in trajectories of change over the course of treatment can help clinicians to better monitor progression toward treatment goals for each patient, as well as more flexibly

adapt the dosage, intensity, and treatment targets tailored to meet individuals' needs in a more time-efficient manner. Furthermore, determining responder neural profiles to treatment at baseline is important, especially in children where brain plasticity and windows of opportunity become increasingly sparse over the course of development, further enhancing the difficulty for interventions to effectively elicit therapeutic changes. Expanding clinical research to better characterize neural signatures that predict response to treatment can help guide clinicians when selecting an appropriate intervention type for the individual in question, and therefore serve as an important clinical tool in future pediatric psychiatry.

To further widen the evidence base for neural signatures of treatment response, as well as to increase the dissemination of affordable ways to identify reliable neural signatures of treatment response to the community, future directions and considerations are outlined. Current advancements in identifying neural signatures of PRT have solely relied on the use of fMRI, which provides good spatial resolution to help identify brain regions of interest. However, fMRI is very expensive and lacks good temporal resolution to resolve the sequence of subprocesses underlying any neural response. A practical implication to consider is the relatively low success rate for young children with ASD to complete fMRI scans, even after extensive training and preparation, as they often show elevated levels of head motion that affect the quality of images collected for analyses. Therefore, future research should continue to look to integrate other more cost-effective neuroimaging tools with enhanced temporal resolution and higher success rates for completion, such as EEG and eye-tracking, to gain insight into not only which areas might serve as neural signatures of treatment response, but how these atypical neural activations might sequentially interact to affect overall neural efficiency in the processing of social stimuli.

One limitation of the current published findings is that participants have been high-functioning children with ASD ($IQ > 70$). Future studies should use larger samples with more heterogeneous symptomatology and a wider range of cognitive levels, to examine the generalizability of

results to lower-functioning children with ASD. Another major limitation is the lack of inclusion of either a waitlist control group, or a group that receives an alternative form of intervention. Inclusion of a waitlist control group of children well-matched on ASD symptomatology, age, IQ, and gender is critical to ensure that neural signatures showing changes in response to social stimuli are truly reflective of the therapeutic effects of the target intervention, rather than associated with general effects of development over the passage of time. Future studies should also include stringent control groups to better address the question of *specificity* of neural signatures of treatment response in children with ASD. Furthermore, inclusion of an alternative form of intervention will address the question of *specificity* of the neural signatures identified, to determine whether they are predictors of treatment response specific to PRT, or whether they may be neural signatures more broadly reflective of improved social cognition following interventions that target social skills in children with ASD. All of these future developments will further advance the field of clinical research toward the goal of developing precision medicine in pediatric psychiatry.

Neurexin 1

Ellen J. Hoffman

Albert J. Solnit Integrated Training Program, Yale Child Study Center, Program on Neurogenetics, Yale School of Medicine, New Haven, CT, USA

Synonyms

NRXN1

Definition

Neurexin 1 (NRXN1) is a candidate gene in autism spectrum disorders (ASD). *NRXN1* is one of three members of the neurexin gene family, which encodes a group of cell adhesion molecules that are found at the synapses of nerve cells. Each neurexin gene can produce two types of neurexin proteins, both a long and a short version, which are referred to as α - and β -neurexins, respectively. Interestingly, the structure of neurexin genes is such that it is possible for one gene to generate many different protein isoforms due to the alternative splicing of RNA transcripts. This means that combinations of neurexin isoforms can result in tremendous diversity at synapses at the molecular level (Sudhof 2008).

There is growing interest in neurexins because they bind to *neuroligins*, another family of cell adhesion molecules that have been strongly implicated in ASD. Specifically, neurexins are present in the presynaptic region, while neuroligins are found postsynaptically, i.e., on the opposite side of the synapse. The interaction of neurexins and neuroligins is likely to play an important role in the formation of synapses. Moreover, neuroligins interact within the postsynaptic cell with members of the SHANK family of proteins, which have also been found in independent studies to be candidate genes in ASD (e.g., *SHANK3*) (Sudhof 2008). Taken together, the identification of *NRXN1* and neuroligins, such as *Neuroligin 4, X-linked (NLGN4X)*, as candidate genes indicates that cell adhesion molecules found at the synapse, and synaptic functioning in general, may represent common pathways in the biology of ASD.

A number of studies have implicated *NRXN1* in ASD. These studies identified rare variants disrupting *NRXN1* in affected individuals at level of the DNA sequence and at the structural level in chromosomes (Feng et al. 2006; Glessner et al. 2009; Marshall et al. 2008; Szatmari et al. 2007). Three of these studies used genome-wide, array-based cytogenetics to identify *copy number variants* (CNVs) associated with ASD. One study found a 300 kilobase deletion, which occurred *de novo*, disrupting *NRXN1* in two affected female siblings (Szatmari et al. 2007), and other identified deletions disrupting *NRXN1* that were

inherited by affected individuals (Glessner et al. 2009). CNVs disrupting *NRXN1* were not found in unaffected individuals (Glessner et al. 2010; Szatmari et al. 2007). Another study identified CNVs at *NRXN1* in individuals with ASD that were *de novo* and inherited (Marshall et al. 2008). However, this study also reported finding structural variation at *NRXN1* in a control population (Marshall et al. 2008).

The strength of the rare variant approach taken by these studies is that finding outliers which occur at a frequency of <5% in the general population favor the discovery of mutations with relatively large effect sizes. However, because these mutations are by definition rare, they are likely to occur in only a very small proportion of individuals with idiopathic ASD (State 2010). In addition, neurexins and neuroligins have been implicated in other psychiatric disorders. CNVs affecting *NRXN1* have been identified in individuals with schizophrenia, such that *NRXN1* is also considered a risk gene for schizophrenia (Kirov et al. 2009). Moreover, as discussed, CNVs disrupting this gene have been found in unaffected individuals as well (Marshall et al. 2008). While these findings are difficult to interpret, they are consistent with *pleiotropy* as an emerging theme in the genetics of ASD. According to this model, variation in risk genes may predispose to a range of clinical presentations due to interactions with other genetic and environmental factors (State 2010). Most importantly, the identification of candidate genes, such as *NRXN1*, has the potential to illuminate common biological mechanisms that underlie these disorders. Therefore, the identification of neurexins and neuroligins as risk genes has led investigators to focus on studying synapse function as a potential common pathway that may contribute to the biology of a range of psychiatric disorders in addition to ASD.

Historical Background

Most of what we know about the neuroanatomy of autism is derived from two sources: neuropathologic analyses of autistic brain tissue and structural MRI studies of populations of living patients with autism. By far, the latter provide us with the most information as MRI provides a noninvasive methodology allowing anatomic analysis of the whole brain in a large sample at multiple time points. Despite these potential advantages, early structural MRI studies of autism have been hampered by small, cross-sectional samples and differing techniques in the face of great clinical heterogeneity and change over the developmental span. For practical reasons, most imaging studies have been performed on higher-functioning adults with autism (a diagnosis of autism cannot usually be made until at least 2 years of age). Therefore, there is scant representation of the developmental periods (gestation and infancy) in which most brain abnormalities seem to emerge in autism (see below). Furthermore, because most studies are restricted to high-functioning individuals with autism, existing differences could theoretically be too subtle to detect. However, despite variable and inconsistent findings, some intriguing patterns have emerged (see Amaral et al. 2008; Lainhart 2006; Schumann and Nordahl 2011; and Stanfield et al. 2008 for excellent reviews).

Neuroanatomy

Definition

Neuroanatomy is the study of the structure (morphology) and organization of the nervous system. Numerous morphometric studies have implicated perturbations in the processes of neocortical growth and organization in the development of autism.

Current Knowledge

Increased Head/Brain Size (Macrocephaly/Macroencephaly)

Studies examining head circumference (HC) and brain volume (by MRI) in autistic infants and children have demonstrated an abnormal developmental trajectory associated with autism. One of the most consistent neuroanatomic findings in ASD, derived from both structural MRI and post-mortem studies, is an abnormally enlarged brain in a significant subset of young children with autism. Retrospective studies of head circumference (HC) in the fetal (Hobbs et al. 2007) and perinatal (Courchesne and Pierce 2005) periods have generally reported little difference between

infants destined to be diagnosed with autism and control infants. However, by 2–4 years of age, average HC and brain volume (BV) are significantly (10–15%) increased in up to 70% of children with autism. Up to 25% of children in this subset actually meet formal criteria for macrocephaly ($HC \geq 2.0$ S.D. above the mean) and/or megalencephaly ($BV \geq 2.5$ S.D. above the mean) (Aylward et al. 2002; Courchesne et al. 2001; Redcay and Courchesne 2005; Sparks et al. 2002).

These findings are interpreted to be the result of early abnormal growth of the brain in the first 2 years of life before autism is diagnosed. While not yet confirmed directly, recent evidence strongly indicates this is the case. One large-scale, longitudinal study (Hazlett et al. 2011) found no difference in growth rates between autistic children and controls from the age of 2 years until 4–5 years. Rather, abnormal brain enlargement was already established by the age of 2 in a significant subset of their sample and remained unchanged by the age of 4–5. Interestingly, a recent neuropathologic study of seven autistic children (Courchesne et al. 2011) found that brain overgrowth in these individuals involved a 67% increase in the numbers of neurons in the prefrontal cortex relative to age-matched controls. Neurogenesis, the birth and early proliferation of neurons, is largely a prenatal process. At birth, cortical neurons are typically small so that an appreciable excess might not translate into a significant change in head size. However, in the first years of life, the typical dramatic increase in cytoplasmic volumes (both of the cell body and axons/dendrites) occurring in more than the usual complement of frontal neurons could account for abnormally accelerated brain growth in the first years of life. The first 2 years of life are usually a period of rapid brain growth in infants as neurons undergo significant postnatal growth in cell size and elaboration (actually overproduction) of axons, synapses, and dendrites. The degree of overgrowth appears to be correlated with severity of symptoms (Courchesne et al. 2001, 2003).

Following the initial period of rapid growth, growth rates in autism tend to decline significantly causing an apparent “normalization” of BV by adolescence/early adulthood (Redcay and Courchesne

2005). The functional significance of this is unknown as up to one third of individuals with autism may clinically deteriorate during this period while others may make significant gains in functioning. Mean HC remains slightly elevated into adulthood, and rates of macrocephaly, although lower, do remain increased overall. It must be noted that the above pattern does not hold true for all individuals with autism. Many show typical rates of head and brain growth, and a small subset even meet criteria for microencephaly, although this is more common in the setting of syndromic autism.

Gray and White Matter Compartments

Many investigators have attempted to determine which aspects of brain anatomy (i.e., gray or white matter compartments or structures/regions) contribute most to altered brain size in autism. It must be noted that GM and WM are not separate entities biologically as WM contains the myelinated axons of the neurons whose cell bodies reside in GM regions/structures. Many have noted an overall rostral-caudal (front to back) gradient in early brain growth trajectories. At the time of maximal brain growth during infancy and early childhood, Courchesne et al. (2001) found that cerebral gray matter (GM) and white matter (WM) were both increased by 18% and 38%, respectively. The frontal cortical GM and WM showed the most enlargement followed by the temporal lobe GM and WM and the parietal GM. The occipital GM and WM and parietal GM tended not to vary significantly from controls. Within the frontal lobes, the GM areas most affected were the dorsolateral and mesial prefrontal cortex (Carper and Courchesne 2005).

Similarly, the white matter most affected appears to be the radiate compartment immediately underlying these same prefrontal cortical areas (Herbert et al. 2004), whereas deeper WM and sagittal/bridging white matter (e.g., corpus callosum and internal capsule) are not enlarged. This suggests overgrowth of later-myelinating, intrahemispheric (corticocortical) connections (originating from layer III neurons) with relative sparing of the interhemispheric (layer III) and cortical to subcortical (layers V and VI) connections.

After childhood, WM is no longer increased relative to typically developing controls although

GM volumes remain elevated. It is therefore thought that “normalization” of BV may be due to a decrease in WM relative to GM, a complete reversal of the age-dependent cortical thinning that typically occurs during this period. Cerebral GM thinning is thought to be a sign of increasing maturity and is generally attributed to the concurrent processes of synaptic pruning and myelination. Excess (presumably weaker or imprecise) connections are eliminated during this period as both axon collaterals and terminal arbors are pruned through retraction or degeneration. This is necessary to develop precise functional connections and provide a substrate for neural plasticity. This process may be aberrant in autism, although this has not been demonstrated directly.

Cortical Surface Area/Thickness

Other cortical aspects, such as thickness, surface area, and gyration patterns, have been investigated by MRI and may provide important insights into the developmental mechanisms implicated in autism. Cortical thickness is a function of multiple factors, such as neuronal density, dendritic arborization, myelination, or sharpness of the gray-white junction, operating in various combinations. One study of cortical thickness (Hardan et al. 2006) reported a global increase in cortical thickness in 8–12-year-old autistic children, most pronounced in the parietal and temporal cortices. Other studies have, conversely, found thinning in the same cortical areas in adults. Early overgrowth followed by later loss may be a trend in critical development in autism, but until more large-scale, longitudinal studies are conducted, this remains speculative.

Cortical surface area also seems to be expanded early in autism. In their study of 59 young autistic children, Hazlett et al. (2011) found cortical gray matter volume increases appeared to be due to increased surface area rather than cortical thickness. Similarly, Hardan, Jou, Keshavan, Varma, and Minshew (2004) found an increase in cortical gyration in the frontal lobe. As folding is related to surface area, this finding implicates increased surface area. Abnormal morphology of the sylvian fissure, superior temporal sulcus, and inferior frontal gyrus have also been reported. Cortical surface area is

generally thought to be a function of the number of early, symmetric divisions by radial glial cells immediately prior to the onset of neurogenesis and migration. Minicolumns are the vertical cell columns created by sequential waves of migrating neurons traveling along radial glial fibers during early corticogenesis. It may be that reports of increased numbers of narrow minicolumns (Buxhoeveden et al. 2006; Casanova et al. 2006) in the frontal cortex of autistic brains may be related to these differences in surface area.

Corpus Callosum

Volumetric studies of the corpus callosum have consistently found decreased total, anterior, middle, and/or posterior callosal volumes in children and adults with autism (e.g., Hardan et al. 2000). This may serve to impede interhemispheric connectivity, thereby contributing to the clinical features of autism. These findings are relatively robust when controlling for IQ, BV, and gender.

Limbic System

Decreased hippocampal volumes have been reported in some high-functioning children, adolescents, and adult males with autism relative to age-matched controls and corrected for BV (e.g., Saitoh et al. 2001). The amygdala, likely involved in social cognition functions such as empathy or theory of mind, has been found to be relatively enlarged in children and adolescents with autism but that this difference tends to decrease with age. Furthermore, the degree of early enlargement appears to be negatively correlated with later social and communicative functioning (Munson et al. 2006). Interestingly, these findings may correspond to the neuropathologic findings of Kemper and Bauman (1993), who reported smaller, more packed neurons with attenuated dendritic arbors in many structures of the limbic system (particularly the amygdala, hippocampus, entorhinal cortex, and mammillary bodies) in autistic children.

Cerebellum

By far, the most consistent finding in neuropathologic studies of postmortem autism brain samples is a reduction in the density of cerebellar Purkinje neurons of the cerebellar cortex. This has engendered great interest in the cerebellum, and

numerous neuroanatomic studies of cerebellar volume/morphology have been performed. A handful of small-scale studies initially reported decreased volumes of cerebellar hemispheres; however, these were not replicated when total BV and IQ were controlled for. In contrast, a number of well-controlled studies actually found increased cerebellar GM and WM volumes in high-functioning children and young adult individuals with autism. It must be noted, however, that these findings were also highly sensitive to gender, IQ, and BV (Piven et al. 1997; Sparks et al. 2002).

A number of studies (performed by and reviewed in Courchesne et al. 1994) found specific areal reductions in cerebellar vermis lobules VI and VII in children and adults with autism relative to age-matched controls. Again, these studies were not matched for IQ and BV; however, their findings were replicated in 46 male autistic children with and without intellectual disability (Carper and Courchesne 2000). In their retrospective review of all 78 subjects, Courchesne et al. (1994) found that 87% of the patients had reduction and 13% had enlargement of vermal lobules VI–VII, suggesting that calculated means may be obscuring a bimodal or polymodal population in many of these studies.

Future Directions

In conclusion, despite a growing number of structural MRI studies examining morphology and growth of the autistic brain, only a few relatively consistent trends have emerged. Principle among these is an increased rate of brain growth in infancy and early childhood, predominately in the frontal, temporal and parietal lobes, and cerebellum. This appears to be followed by abnormally slow cerebral and cerebellar growth in later childhood and adolescence. Variable structural abnormalities in the corpus callosum, amygdala, and hippocampus have also been reported. These findings are consistent with the clinical evidence indicating the social and language functions reliant upon functional connectivity among these areas are aberrant in autism. It could be hypothesized that disturbances in early brain developmental processes (e.g., neuronal

proliferation, differentiation, migration, process elaboration, and/or synaptogenesis) underlie abnormal growth trajectories and result in altered brain anatomy and functional connectivity.

In order to overcome the limitations of previous morphometric analyses, future quantitative MRI studies will have to employ very large sample sizes of well-characterized individuals with autism and attempt to image them longitudinally over the developmental span, starting at birth if possible. Rigorous control matching for age, gender, and IQ will undoubtedly continue; however, samples will hopefully be expanded to include lower-functioning autistic and control individuals whenever feasible. Fortunately, significant trends toward this goal are already evident in recent literature. Larger, pooled samples and meta-analyses are increasingly employed. Earlier detection and diagnosis of autism will also be possible as evidenced by findings from at-risk infant sibling studies. Finally, recent computer-based measurement techniques, e.g., high definition fiber tracking, will permit the detection of subtle morphologic differences not appreciated by traditional quantitative/structural MRI studies or even histopathologic examination of brain tissue.

Definition

Neurochemistry is the study of chemicals and their reactions in the nervous system. Potentially a tremendously broad field, neurochemistry could encompass nearly all the anatomy and physiology

of the central and peripheral nervous systems. Practically, “neurochemical” research has tended to focus on endogenous chemicals (especially neurotransmitters) and nongenetic molecular aspects of the nervous system, the pathogenesis of neuropsychiatric disorders, and the identification of disease biomarkers.

Current Knowledge

Neurochemical research in autism has included studies on serotonin, noradrenaline (norepinephrine), dopamine, glutamate, GABA, and cholinergic and stress response systems. Most of the studies have examined levels of neurochemicals in either cerebrospinal fluid, plasma, or urine; only limited postmortem brain data are available and are not definitive.

Research on serotonin has focused on the well-replicated platelet hyperserotonemia of autism and apparent decrease in function and expression of the platelet and brain serotonin type 2 receptor. Global dopaminergic metabolism and functioning appear normal based on the determination of dopamine metabolite levels in plasma and urine and on measurements of the dopamine-modulated hormone prolactin in plasma. Research on stress response systems, including the noradrenergic-sympathetic/adrenomedullary system and the hypothalamic-pituitary-adrenal (HPA) axis, has found basal functioning to be similar in autism and typically developing individuals. However, in autism, the systems appear hyperreactive to stress. Decreased production of melatonin in autism has been consistently reported and focuses attention on circadian processes.

Future Directions

Future research will continue to attempt to understand the underlying causes of the well-replicated platelet hyperserotonemia, the extent and consequences of altered serotonin type-2 receptor expression and function, of possible cholinergic alterations, and the lower melatonin production

seen in autism. In addition, metabolomic studies will attempt to identify patterns of alteration specific to autism. In general, studies will need to take account of the large degree of heterogeneity in the autism category.

Neurodiversity

Nick Chown

Palau-solità i Plegamans, Lliçà de Vall,
Barcelona, Spain

The concept of “neurodiversity” refers to the diversity of neurocognitive and/or sensory functioning differing from that associated with the “neurotypical” population (also known as the “predominant neurotype”). In defining “neurodiversity” one should first consider the meaning of “neurotypical.” Perszyk (2013, p. 1) defines “neurotypical” as:

Description of a medically and psychologically healthy individual demonstrating a normative pattern of neurodevelopment. Typically used specifically in contrast with individuals experiencing an atypical developmental course, such as autism

The implication in Perszyk’s definition that a nonnormative pattern of neurodevelopment is a “psychologically unhealthy” one is incorrect as many neurodivergent conditions simply represent the wide variety of differences amongst humanity. For instance, autistic advocates argue persuasively that autism is an example of ordinary human difference. However, the reference to atypical development in the Perszyk definition captures a majority view of autism and other conditions included within the compass of neurodiversity.

An individual whose cognitive and/or sensory functioning differs from that of the neurotypical population is said to be “neurodivergent,” whereas the concept of “neurodiversity” expresses the diversity of cognitive and sensory functioning and in so doing refers to the entire population, i.e., the concept encompasses neurodivergent people *and* neurotypical people.

Hughes (2015, pp. 5/6) is one of many scholars to define neurodiversity by listing conditions that she considers fall within the ambit of the term. In doing so, she refers to the expansion of a definition “around ‘high-functioning’ autism . . . to describe any kind of cognitive processing or way of making sense of the world that deviates from ‘typical’ ways of thinking and being.” Hughes

describes hers as a narrow definition of neurodiversity. A broader definition in her terms is one that includes all autistic people irrespective of their so-called functioning level. The UK Developmental Adult Neuro-Diversity Association (DANDA) defines neurodiversity as “difficulties with organisation, memory, concentration, time, direction, perception, sequencing. Poor listening skills—leading to low self-esteem, anxiety, depression but creative, original, determined.” DANDA’s definition of neurodiversity is a broad one in Hughes’ terms. The DANDA definition also refers to some of the strengths associated with neurodivergence. Steve Silberman (2015, p. 17) is another author who refers to strengths when defining “neurodiversity” as: “the notion that conditions like autism, dyslexia and attention-deficit/hyperactivity disorder . . . should be regarded as naturally occurring cognitive variations with distinctive strengths that have contributed to the evolution of technology and culture rather than mere checklists of deficits and dysfunctions.” His definition is also of interest for its reference to naturally occurring variations.

Taken literally, the term “neurodivergence” could also encompass any condition marked by a difference from the typical condition of the human nervous system (including brain, spinal column, and peripheral nerves). For example, many conditions causing physical impairment, such as cerebral palsy, Parkinson’s disease, or multiple sclerosis, could be included. However, these “physical neurological” conditions are generally not included within the concept of neurodivergence. This is perhaps in part because the interests of people with such conditions are generally represented by disabled people’s movements which have historically centered around people with physical impairments and related access or assistance needs. The neurodiversity movement evolved separately from these disabled people’s movements, though arguably with some conceptual roots in them (Graby 2015). However, the absence of these conditions from the scope of “neurodivergence,” as commonly used, does call into question the accuracy of the “neuro” part of this term.

Some people are beginning to identify with the concept of neurodiversity who have been

classified by psychiatry in categories more commonly associated with “mental health” than with “disability” (such as “schizophrenia” and “bipolar disorder”). For example, Suzanne Antonetta, who was diagnosed with “bipolar disorder,” gave her 2005 book *A Mind Apart* – which describes her experience, and that of autistic author, Dawn Prince-Hughes, as well as those of friends with diagnoses such as “dissociative identity disorder” (formerly known as “multiple personality disorder”) – the subtitle “Travels in a Neurodiverse World.” An online community of self-defined “multiples” also exists, who see their separate “personalities” not as a dissociative pathology but as different “people” sharing a brain and body, each of whom has a right to exist. This has links to, and overlaps with, the autistic and broader neurodiverse communities (Baggs et al. 2006), although it should be noted that not all proponents of neurodiversity accept that the term should be as broad as this.

Finally, we should draw attention to the disagreement over whether or not individuals with intellectual disability only (i.e., not autistic, dyslexic, dyspraxic) should be classed as neurodivergent. We believe the majority of scholars regard such individuals as neurotypical but are aware that some scholars argue that these individuals are neurodivergent.

There are no definitive definitions in relation to neurodiversity.

Neuroligins

Abha R. Gupta¹ and Nicholas M. DiLullo²

¹Developmental-Behavioral Pediatrics, Child Study Center, Yale University, New Haven, CT, USA

²Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Synonyms

NLGN1; NLGN2; NLGN3; NLGN4X; NLGN4Y

Structure

Neuroligins are a family of proteins which are expressed in the brain at the surface of nerve

cells. There are five members as follows, ranging in size from 823 to 853 amino acids in length:

NLGN1 located at chromosome 3q26.31

NLGN2 located at chromosome 17p13.1

NLGN3 located at chromosome Xq13.1

NLGN4X located at chromosome Xp22.32

NLGN4Y located at chromosome Yq11.221

Neuroligins are postsynaptic membrane proteins in the nervous system. In other words, they exist on the outside membrane of the nerve cell which receives information in the form of chemical neurotransmitters from presynaptic cells. They are classified as type 1 membrane proteins; therefore, they pass from the outside of the cell through the membrane to the inside of the cell exactly once, unlike some proteins which pass through the membrane two or more times. The amino acid structure consists of a large N-terminal extracellular domain followed by a single transmembrane region and a short cytoplasmic sequence. The extracellular domain consists of an acetylcholinesterase (AChE)-like domain which is the site for extracellular binding (Lise and El-Husseini 2006). Mutations in *NLGN3* and *NLGN4X* have been implicated in autism spectrum disorders (ASDs). They are known binding partners of β -neurexins, which in turn complexes with Shank (SH3 and multiple ankyrin repeat domain) molecules, two other neuronal proteins which have also been associated with ASDs. These molecules provided among the first evidence that the neural synapse may be dysfunctional in ASDs.

Function

In addition to serving as cell adhesion molecules across a synapse, neuroligins have an important role in synapse formation. They bind to β -neurexin, a protein which exists on the presynaptic side of the synaptic cleft. This binding helps lead to the connection between two nerve cells and the creation of a synapse (Fabrichny 2007). On the inside of the postsynaptic cell, neuroligins bind to Shank, a structural protein which also

plays an important role in the development and support of the synapse. It has been shown that the different neuroligins express at different points during development. Neuroligins 3 and 4 express significantly during the fetal stage, whereas neuroligin 1 expression increases in the childhood years into adulthood (Sudhof 2008). In addition, neuroligins have been suggested to play a role in the formation of new blood vessels from pre-existing vessels (Bottos et al. 2009).

Pathophysiology

Thomas et al. (1999) reported on three girls with ASD who had deletions in the short arm of chromosome X. Upon further examination, the deleted region was revealed to contain the gene *NLGN4X*. This was the first evidence that neuroligins may be related to ASDs.

Jamain et al. (2003) found two deleterious mutations in neuroligin genes. The first was in a Swedish family with two affected brothers, one with Asperger syndrome and one with autism. Both of the brothers had the same mutation in *NLGN4X* which was inherited from their mother. This mutation was not found in any other family members, including the unaffected brother, and not in 350 unrelated controls. This de novo mutation in the mother resulted in a premature stop codon approximately halfway into the sequence and truncated the protein. It completely deleted the transmembrane portion of the protein. The mutation may not have had a significant impact on the mother because she had a second normal copy of *NLGN4X* on her other X chromosome. A missense mutation in *NLGN3* was identified in a second Swedish family. This mutation was also maternally inherited by two brothers, one with Asperger syndrome and one with autism. This mutation caused an amino acid change resulting in a nonfunctional esterase domain, impairing its ability to bind neurexin. This mutation was not found in any of the 200 control individuals used for the study. The mutations found in this study are very damaging and highly suggestive that *NLGN3* and *4X* have a significant impact on neurodevelopment. Numerous studies since have

been published examining *NLGN* mutations in other cohorts; they continue to be an important source of rare mutations in ASD.

Scientists have created *NLGN3* knockout mice, meaning that these mice do not have a functional copy of the *NLGN3* gene. They have decreased brain size and, behaviorally, show decreased context and cued conditioning, hyperactivity, abnormal social skills, and vocalization (Radyushkin et al. 2009). Replicating symptoms similar to those in humans with a *NLGN3* deficiency lends further evidence to the case that mutations in *NLGNs* contribute to the development of ASD.

Neurologist

Nancy J. Minshew
Departments of Psychiatry and Neurology,
University of Pittsburgh, Pittsburgh, PA, USA

Definition

A physician specializing in the evaluation and treatment of disorders of the nervous system, e.g., disorders of the brain, spinal cord, peripheral nerves, and muscles. In the USA and Canada, these specialists have received an M.D. or D.O. degree followed by 1–3 years of pediatric or internal medicine training and then a 3-year fellowship in neurology. The neurology training can focus entirely on adults or can have an emphasis on children. Following specialty training, board certification is available in neurology or neurology with special competence in child neurology. Thereafter, the individual can practice general adult or general child neurology, or pursue subspecialty training in a wide range of areas such as behavioral neurology, genetics, epilepsy, developmental disabilities, geriatrics, stroke, dementia, etc. In addition, there are neurologists who have also completed a Ph.D. in an area of interest that confers additional expertise. Training systems differ somewhat in other countries.

Neurologists may be consulted for the evaluation and treatment of headaches, epilepsy or seizures, deterioration in function, learning

disabilities, cerebral palsy, delayed or abnormal development, weakness, and a range of signs and symptoms that suggest a brain, spinal cord, peripheral nerve, or muscle origin. Neurologists are often consulted in the assessment of an individual with ASD when the possibility of seizures is raised or in cases of regression to determine specific etiologies other than ASD that may require a specific treatment or have different genetic implications. It is important that the neurologist evaluating an individual with ASD or suspected of having ASD has expertise and experience in ASD. Neurologists also contribute to research in autism (articles listed below provide a few examples of these contributions).

Neurontin (Gabapentine)

Jonathan Kopel
Texas Tech University Health Sciences Center
(TTUHSC), Lubbock, TX, USA

Synonyms

[Neurontin](#)

Definition

Among Autism Spectrum Disorder (ASD) patients, insomnia and disruptive-compulsive behaviors remain difficult to manage from limited efficacy or adverse side effects with current

pharmacological therapies (Blackmer and Feinstein 2016; Brown and Malow 2016; Guglielmo et al. 2013; Kotagal 2012). In recent years, antiepileptic drugs, specifically gabapentine, have become increasingly utilized for impulsive and aggressive behavior among neurodevelopmental disorders (Guglielmo et al. 2013). Gabapentin is an amino acid derivative used to treat anxiety disorders, alcohol dependence, insomnia, obsessive-compulsive disorder, and somatoform disorder (Guglielmo et al. 2013). Current research suggests gabapentin's acts through α^2 - δ subunits of voltage-gated calcium channels, which modulate synaptic homeostasis within the nervous system (Guglielmo et al. 2013; Wang et al. 2016). Although effective, large-scale trials of gabapentine are needed to determine its efficacy and safety for ASD and other neurodevelopmental disorders.

Neuropathology

Kate McFadden

Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Definition

Neuropathology is the scientific study of disorders of the nervous system. Neuropathologic studies of autism spectrum disorders (ASD) are conducted on postmortem brain tissue obtained from individuals who were diagnosed with an ASD during life as well as normal controls. Tissue from each donor individual is stored in special research banks, both fixed (for microscopic anatomic and antibody expression studies) and frozen (for molecular and biochemical studies).

Historical Background

Due to early issues of variation in diagnostic precision, tissue availability, collection protocols, sample demography, postmortem interval, and research goals, early postmortem research into ASD is mainly represented by scattered case studies or small series of individuals with relatively poorly documented autistic features or ill-defined syndromes. Although conditions for ASD researchers have improved greatly due to coordinated tissue collection and banking efforts, neuropathologic studies continue to be hampered by small sample size in the face of great underlying heterogeneity in etiology, comorbidity, and sampling. For these reasons, less than 100 brains have been examined to date and have yielded somewhat inconsistent, albeit intriguing results.

The first detailed postmortem report of a well-documented, nonsyndromic case of ASD was published in 1985 by Bauman and Kemper. After completing 10 additional cases over the next decade (reviewed in Kemper and Bauman

1993), three common findings emerged: (1) increased brain weight in children and decreased brain weight in adults, (2) increased packing densities of smaller-sized neurons (with underdeveloped dendritic arbors) in select forebrain structures such as the anterior cingulate gyrus, and (3) decreased numbers of Purkinje neurons in the cerebellum. These findings have been replicated and expanded upon by more recent research, outlined in the next section.

Current Knowledge

Autism and its clinically similar spectrum disorders (ASDs) are now conceptualized as developmental neurobiological disorders affecting elaboration of the forebrain circuitry that underlies those abilities most unique to human beings. The development of neural circuitry depends upon the coordinated interactions of numerous genetic/molecular cascades and environmental/experiential exposures. At the basic level, the physical substrate of neural circuitry is provided by neurons, their processes (axons and dendrites), and their synapses on neighboring or distant neurons. Wiring the brain requires that neurons proliferate, acquire the correct laminar identities, migrate to the appropriate locations, extend axons which must make guidance decisions with a high degree of spatial and temporal fidelity, and finally, establish synaptic connections with appropriate target neurons. Neuropathologic studies have reported subtle abnormalities in multiple brain regions (cerebral cortex, cortical white matter, limbic structures, brainstem, and cerebellum), indicating more than one of the abovementioned pre- and early postnatal developmental processes may be altered in various combinations to produce the heterogeneous phenotypes observed in ASD.

Most of the information we have concerning the physical or anatomic substrate of altered connectivity in ASD comes from clinical studies using magnetic resonance imaging (MRI). Structural MRI studies have uncovered ample evidence of altered developmental growth trajectories as well as size differences both of the whole brain and specific structures/compartments in

substantial subsets of adults and children with ASD (reviewed in Lainhart et al. 2006). Most striking is the finding of early overgrowth of the brain in ASD. While not significantly different from controls at birth, up to 70% of infants with ASD exhibit abnormally accelerated brain growth in the first year of life followed by a relative deceleration in age-related growth in some. This is particularly marked in the frontal and temporal cortices and the amygdala.

While these findings strongly indicate altered events in brain development, there is no way to directly attribute the gross findings to these events as MRI technology currently lacks the required resolution. Therefore, complementary neuropathologic studies of postmortem brain tissue are necessary to directly examine alterations in brain microarchitecture which (presumably) reflect the neurobiological underpinnings of ASD at the neuronal level. “Complementary” because there are both advantages and drawbacks to tissue-based research relative to structural MRI studies. Histologic studies allow a greater degree of resolution, i.e., the ability to examine neuronal structure, distribution, and gene/protein expression within the same individual. However, they are often more laborious and time consuming, making integrated analysis of the whole brain prohibitive. Despite these difficulties, recent efforts have yielded some fascinating patterns, outlined by region below.

Brain Size

Several neuropathologic studies have replicated the MRI findings of early increased brain growth followed by deceleration or, occasionally, persistence of macrocephaly in individuals with ASD as evidenced by increased brain weight. The white matter below the frontal lobe is enlarged in young children with autism but not in adults as assessed by structural imaging (Herbert et al. 2004). Kemper and Bauman noted that the brain weight of younger autistic individuals was significantly greater than comparable controls. Bailey et al. (1998) likewise noted increased brain size/weight in some young adults. A recent preliminary report of seven autistic children (Courchesne et al. 2011) found that brain overgrowth in these individuals involved a 67% increase in the numbers of

neurons in the prefrontal cortex relative to age-matched controls. Neurogenesis, the birth and early proliferation of neurons, is largely a prenatal process. At birth, cortical neurons are typically small so that an appreciable excess might not translate into a significant change in head size. However, in the first years of life, the typical dramatic increase in cytoplasmic volumes (both of the cell body and axons/dendrites) occurring in more than the usual complement of frontal neurons could account for abnormally accelerated brain growth in the first years of life.

Cortex

Besides recent findings, discussed above, of excess neurons in the prefrontal cortex of autistic children, more than half of all *postmortem investigations have uncovered* features of cortical dysgenesis, i.e., abnormalities of neuronal layering or distribution caused by dysregulation of neurogenesis, neuronal migration, or maturation, in ASD brains. In the seminal postmortem studies by Kemper and Bauman, the only consistent abnormality in the cerebral cortex was small neuronal cell size and increased cell packing in the anterior cingulate cortex (ACC) in five of six subjects with ASD compared to age-matched controls. The ACC, a component of the limbic system involved in monitoring of social interaction, is one of the cortical areas most consistently associated with abnormalities in imaging and neuropathologic studies. Using stereologic techniques, Simms, Kemper, Timbie, Bauman, and Blatt (2009) variably found decreased cell size and decreased cell packing in different subregions of the ACC. Other findings included irregular lamination, increased subcortical white matter neurons, and densities of von Economo neurons that were either significantly more or less than seen in age-matched controls. Avino and Hutsler (2011) similarly found a poorly defined boundary between gray matter and white matter in the dorsolateral frontal and parietal cortices as well as the superior temporal gyrus. Van Kooten et al. (2008) conducted a stereologic study on the fusiform gyrus, involved in face processing, and found significantly lower neuronal densities within layer III and lower total neuron numbers in layers

III, V, and VI, as well as smaller average cell volumes of neurons in layers V and VI.

Bailey et al. (1998) observed more significant and widespread cortical dysgenic lesions in four of six subjects with ASD. These included a thickened cortical ribbon, increased neuronal densities, gray matter heterotopias, excess neurons in the molecular layer and subcortical white matter, and irregular lamination. Increased brain size and weight, present in four of the subjects, tended to be associated with the presence of heterotopias. Similarly, in a recent large-scale study, Wegiel et al. (2010) reported a wide variety of dysgenic lesions and heterotopias in multiple cortical regions in 12 of 13 subjects with ASD. These included excessive ongoing neurogenesis (evidenced by a thickened subependymal layer or subependymal nodular dysplasia), subcortical and periventricular heterotopias, as well as other disruptions of the cytoarchitecture. Differences in neuronal morphology have also been noted in the cortex. Hutsler and Zhang (2010), counting dendritic spines on individual cortical pyramidal neurons, found increased spine densities in the temporal lobes of individuals with ASD and intellectual disability relative to age-matched controls. ASD subjects with either mild or no intellectual disability were similar to controls.

Recent studies have also found subtle but pervasive microstructural abnormalities in cortical architecture, even in the absence of more obvious dysgenic lesions. Although most of these analyses are not rigorously stereologic, the impression is of increased numbers of narrow minicolumns containing increased densities of neurons (Buxhoeveden et al. 2006; Casanova et al. 2002, 2006) in the frontal cortex of ASD brains. This trend appears to be most pronounced in the frontal lobe, particularly the dorsolateral prefrontal cortex, and is not seen in more posterior regions such as the visual cortex. Minicolumns are the vertical cell columns created by sequential waves of migrating neurons travelling along radial glial fibers during early corticogenesis. Increased numbers of such arrays may reflect excess early divisions of radial glial cells immediately prior to the onset of neurogenesis and migration. Furthermore, the distribution of minicolumn

abnormalities correlates with patterns of accelerated growth in the early postnatal period (i.e., frontal > posterior) and, so far, the excess neurons reported in the prefrontal cortex of young males with autism (Courchesne et al. 2011). Again, while probably not detectable at birth, the presence of even a small proportion of excess neurons could conceivably cause rapid postnatal growth in frontal regions.

In a recent study, (Zikopoulos and Barbas 2010) stereologically investigated the fine structure by light and electron microscopy (EM) of myelinated axons in the white matter below the ACC, orbitofrontal cortex (OFC), and lateral prefrontal cortex (LPFC). They found similar overall axonal density between normal and ASD groups below all prefrontal areas. However, the ASD group had significantly fewer large axons (many presumably representing long-range corticocortical connections) in the deep white matter below the ACC associated with a significantly greater density of smaller axons (thought to connect adjacent cortical areas) in the corresponding superficial white matter. There were no discernable differences in neuronal densities or distributions in the overlying gray matter. The white matter below ACC also exhibited a significantly higher proportion of branched axons of medium caliber. This corresponded to higher levels of GAP-43 expression. Axons in the superficial white matter below the OFC exhibited significantly thinner myelin sheaths when controlled for axon diameter despite similar numbers of oligodendrocytes (the glia responsible for myelination).

Limbic System

As in the ACC, Kemper and Bauman (1993) reported smaller, more packed neurons with attenuated dendritic arbors in many other structures of the limbic system (particularly the amygdala, hippocampus, entorhinal cortex, and mammillary bodies) in autistic individuals relative to age-matched controls. In contrast, septal neurons were unusually large in young autistic children but relatively smaller and depleted in numbers in autistic adults. Bailey et al. (1998) found increased cell packing in the hippocampus

of one out of five cases. The findings in the amygdala may correspond to MRI reports of early enlargement of the amygdala; however, (Schumann and Amaral 2006) found a 15% decrease in the number of neurons in the amygdala of adolescents and adults with autism in their stereologic study, thereby indicating the possibility that neuron number is either not responsible for the increase in amygdala size in young autistic children or that significant neuron loss occurs starting in adolescence. Given the trends seen in the septum, the latter may be plausible. Wegiel et al. (2010) additionally found dysplastic laminar irregularities in the hippocampus of four brains, again implicating subtle irregularities in neuronal migration.

Cerebellum

By far, the most consistent finding in neuropathologic studies of postmortem ASD brain samples is a reduction in the density of cerebellar Purkinje neurons of the cerebellar cortex (Bailey et al. 1998; Kemper and Bauman 1993; Palmen et al. 2004, and many others), although there is no discernable clinical correlate of this abnormality. Kemper and Bauman first described a decrease in the number of Purkinje cells in all the autistic brains they analyzed regardless of age. This was particularly marked in the posterior-lateral part of the lateral lobes. The neurons of the deep cerebellar nuclei (the targets of Purkinje cell projections) were abnormally large in younger individuals and abnormally small, and sometimes reduced in number, in older individuals. It must be noted that these studies have not been strictly stereologic and not always replicated. For instance, Fatemi et al. (2002) reported no difference in Purkinje neuron density but did note an approximately 25% reduction in cell size. Whitney et al. (2009) found that only a proportion of their cases of ASD showed reduced Purkinje cell densities as well as decreases in basket and stellate cell densities. Wegiel et al. (2010) reported variable occurrences of cerebellar flocculonodular dysplasia, focal vermal dysplasia, cerebellar hypoplasia, and cerebellar heterotopias, indicating that evidence of altered neuronal migration could also be found in this structure.

Brain Stem

Kemper and Bauman (1993) reported similar alterations in the inferior olive as detected in the septum and deep cerebellar nuclei. Younger ASD brains exhibited unusually large neurons in the inferior olive, whereas in the adult cases, these neurons were small and pale. The overall numbers of inferior olivary neurons were similar to controls in both instances but tended to be concentrated at the nuclear periphery – the part of the complex that projects to the posterior-lateral part of the lateral lobes of the cerebellum. The synaptic relationship between the olivary and Purkinje neurons is established at approximately 28 weeks of gestation and is tight to the point that if Purkinje cells die for some reason, there is retrograde loss of the corresponding olivary neurons. Therefore, they reason, the “loss” of Purkinje neurons in ASD predates the formation of this relationship as olivary neuronal numbers do not appear to be reduced. While the mechanism for this is not understood, the age-related changes in neuronal size in the cerebellar nuclei, inferior olive, and septum are evidence of ongoing alterations in developmental processes, at least before adulthood. Bailey et al. (1998) reported olivary dysplasia or ectopic olivary neurons in five cases of ASD.

Future Directions

In conclusion, relatively consistent neuropathologic observations in autism have included early increased brain size associated with increased numbers of prefrontal neurons, more densely packed smaller neurons in the limbic system, decreased numbers of cerebellar Purkinje neurons, and features of neuronal lamination/migration disturbances – all of which may be traced to prenatal disturbances in brain development. The identification of substantial trends is actually quite remarkable given the staggering heterogeneity in core and comorbid clinical features of ASD and demonstrates the great promise neuropathologic studies hold for identifying the elusive developmental neurobiological underpinnings of altered connectivity in ASD.

For this promise to be fulfilled, future studies will have to be increasingly systematic – employing rigorous stereologic and molecular neuropathologic methods, e.g., large-scale as well as single-cell gene and protein expression analyses. This will require larger samples of ASD brain tissue, derived from a broader age range, in order to provide the necessary statistical power to contend with distinct clinical and genetic subphenotypes as well as dynamic changes observed over the developmental lifespan by structural MRI. Fortunately, significant trends toward this goal are already evident in recent literature, fueled by noteworthy improvements in the availability and quality of ASD postmortem brain tissue through efforts such as the Autism Tissue Project.

Structure

Neural Structures Implicated Through Neurophysiological Assessment in ASD

The study of neurophysiology in ASD has implicated specific brain structures, such as the superior temporal sulcus in association with processing biological movement, the fusiform gyrus in relation to face processing, the anterior cingulate cortex in relation to joint attention abilities, and the cerebellum in attention and engagement, among others. Neurophysiological studies have also implicated brain regions such as the limbic system, including the amygdala and hippocampus in relation to affective processing and memory, the mirror neuron system in relation to action understanding and imitation, and the ventromedial prefrontal cortex in association with stimulus-reward associations.

Function

Neurophysiological Tools and Measurements

Neurophysiology concerns the study of the functions of the nervous system. Neurophysiological measures are utilized to examine both brain

structures and neural pathways. Methods such as electroencephalography, electromyography, and assessment of skin conductance provide information about various aspects of the nervous system including sensory, motor, and cognitive functioning. Neurophysiological studies provide important information about the connections between brain structures and systems as well as what areas and networks of the brain may be impacted in individuals with disabilities such as autism spectrum disorder.

Electroencephalography (EEG)

One of the primary methods for studying neural pathways in the brain is electroencephalography (EEG), which is the measurement of electrical activity produced by the brain. EEG is recorded from the scalp and is a noninvasive method of measuring postsynaptic neuronal activity. EEG recordings reflect the propagation of electrical activity to the scalp from the synchronous activation of a specific population of neurons.

EEG can provide important information about the functioning of neural networks. EEG oscillatory activity, measured by the frequency and amplitude of synchronized neural activity, reveals information about the state of the brain. Evoke potentials (EPs) and event-related potentials (ERPs) are the result of averaging EEG activity to examine time-locked responses to the presentation of a stimulus (visual, somatosensory, or auditory). EEG coherence refers to the functional connectivity of neural networks measured by the relation of signals over distal neuronal regions.

EEG is a noninvasive technique in which the individual wears an electrode net on the scalp while observing/listening to stimuli or simply resting. EEG has excellent temporal resolution but relatively poorer spatial resolution compared to other imaging modalities. EEG studies of individuals with ASD allow us to better understand the timing of brain functioning, alterations in resting and active brain states, and potential under- and overconnectivity of the brain. EEG studies can be designed such that individuals do not need to make a behavioral, motor, or vocal response, allowing for the use of the method across age groups, cognitive and verbal functioning, and the autism spectrum. In addition, it has

the added benefit of being able to examine neuronal processing over time to better understand the stages of processing of a phenomenon.

Electrooculogram (EOG)

By recording activity from electrodes placed around the eye, eye movements can be carefully characterized and studied. Eye movement studies provide information about the cortical and subcortical regions of the brain that control eye movement activity. For instance, studies that examine saccadic (e.g., fast) eye movements are able to assess frontal brain regions as well as the brain stem and cerebellum, whereas voluntary eye movements and pursuit eye movements (used for visual tracking) can determine if anterior and posterior regions are involved. These basic visual processes can also be studied using eye tracking.

Electromyography (EMG)

EMG is a noninvasive technique used to measure and record the electrical activity of skeletal muscles. This has implications for neurophysiological functioning through the use of experimental paradigms. Fear potential startle response (FPS) is a noninvasive psychophysiological methodology that has been widely utilized in the non-ASD population to facilitate better understanding of amygdala functioning. In FPS, a sudden onset of an acoustic, visual, or tactile stimulus elicits a startle response. Acoustic startle amplitude can be enhanced by exposure to a conditioned stimulus that was paired with an aversive stimulus. This conditioned stimulus or signal produces a state of fear that potentiates the startle response and increases reflexive behavior. The threat cue primes an individual for response, creating a fear state, manifested by an exaggerated startle reflex to any suddenly imposed stimulus (Lang et al. 2000). The startle response is characterized by a fast series of muscle contractions around the head, neck, and shoulders; the first, fastest, and most stable component in this reaction is a sudden closure of the eyelid (Minshew et al. 1999). Intensity of the startle response is measured by electromyographic activity of the orbicularis muscle during the eyeblink, or blink magnitude (Lang et al. 1990).

Skin Conductance

The assessment of the electrical conductance of the skin, which varies with its moisture level, is called skin conductance or the galvanic skin response (GSR). The measurement of GSR provides insight into physiological arousal levels and the sympathetic nervous system as the sweat glands are controlled by the sympathetic nervous system.

Electrocardiography (ECG)

ECG is the measurement of heart rate and blood pressure.

Magnetoencephalography (MEG)

MEG is a method of recording neural activity by recording magnetic fields produced by electrical currents in the brain. MEG records neuronal activity directly and has high temporal (<1 ms) and spatial resolution (1–5 mm), making it a useful tool for neurophysiological research. MEG can be used to examine temporal correlations or coherence within a particular brain region or across regions as well as auditory processing deficits in ASD.

Pathophysiology

Processes Elucidated Through Neurophysiological Assessment in ASD

Visual Processing

Individuals with ASD have often been described as having altered perceptual processing. An ERP study of children with ASD found a faster early visual component (C1) (thought to be generated by the primary visual cortex) to simple sinusoidal luminance patterns compared to typically matched controls (Milne and Scope 2008). This is thought to reflect faster visual perceptual detection in individuals with ASD, suggesting that activity in the primary visual cortex may be enhanced compared to typically developing individuals. However, individuals with ASD may demonstrate perceptual impairment in extrastriate cortex (V2). Studies have found that individuals with ASD show decreased specialized processing

of visual frequencies, decreased extrastriate activity, and reduced perceptual boundary detection (Vandenbroucke et al. 2008; Boeschoten et al. 2007). Bertone et al. (2005) suggest that individuals with ASD have difficulties with integration of visual information.

Eye movement studies have found that children with ASD make more saccades in passive viewing tasks than typically developing children (Kemner et al. 1998). Minshew et al. (1999) found that adults with ASD had significant abnormalities in volitional eye movements, indicating frontal dysfunction rather than cerebellum dysfunction since visually guided saccades (which are governed by the cerebellum) were normal. These findings suggest that the basic attentional and sensorimotor system may be intact in ASD and that difficulties in attention shifting may be due to frontal dysfunction and executive functioning abilities. Studies of pursuit eye movements, which rely on multiple brain systems, provide insight into functional connectivity in ASD. A study of pursuit eye movements found bilateral pursuit deficits in individuals with ASD, suggesting that there may be abnormalities in connectivity in the sensorimotor domain possibly due to abnormal brain maturation (Takarae et al. 2004).

Face Processing

ERPs can be used to better understand both low-level perceptual processing of faces as well as more complex cognitive processing. Young children with ASD show delayed social processing of faces but intact processing of objects. Webb et al. (2010) found that 18–30-month-old children with ASD had ERP responses to familiar and unfamiliar faces that were more similar to younger neurotypical children; the authors suggested that ERPs could be used to document the nature of delays in basic social processing. This response changes in development similar to neurotypicals, but may continue to be delayed. Electrophysiological studies have also found altered patterns of early stage components when adolescents and adults with ASD process faces such as a slowed N170 (an ERP component that is evoked to faces in typically developing individuals) (McPartland

et al. 2004; O'Connor et al. 2007), but not when the eye region was cued before stimulus onset (Webb et al. 2010). Overall, ERP studies of individuals with ASD suggest both abnormal processing speed and cortical organization for processing faces both in early and later stage processing components, but mixed results in adulthood when compensatory strategies may allow more normative brain activation.

Facial Emotion Processing

ERPs allow examination of the neural network underlying emotional processing by measuring brain responses to emotionally salient stimuli. ERP studies of younger children with ASD suggest delayed processing speed and atypical recruitment of cortical areas for processing facial emotion. Dawson, Webb, & Carver, Panagiotides, and McPartland (Dawson et al. 2004) found that 3–4-year-old children with ASD showed a slower early brain response to fear faces and failed to show a larger amplitude, negative slow wave response to fearful faces seen in typically developing children. In addition, children with ASD who exhibited a faster early component processing speed demonstrated better social attention, suggesting a relationship between speed of processing emotional stimuli and social attention impairments in children with ASD. This finding suggests early ASD is associated with abnormal processing of facial expressions of emotion and that these abnormalities begin at early stages of processing. In older children, differential processing of emotions via ERPs has not shown pervasive impairments in ASD. Wong et al. (2008) found normal patterns of ERP and behavioral responses to emotional expressions. However, using source localization, the children with ASD showed slower and weaker responses to emotional expressions in regions responsible for face perception and emotion processing (Wong et al. 2008).

Connectivity

Theories of ASD have conceptualized the disorder as an impairment in connections among neural systems (Belmonte et al. 2004; Rippon et al. 2007; Courchesne and Pierce 2005; Just et al. 2004).

EEG measures of coherence assess communication across neural populations by examining spontaneous activity across predefined frequency bands that represent the speed of neural oscillations; these frequencies include delta (< 4 Hz), theta (4–8 Hz), alpha (8–12 Hz), beta 1 (12–20 Hz), beta 2 (20–30 Hz), and gamma (30–80 Hz). An examination of cortical connectivity in adults with autism found globally reduced EEG coherence in the alpha range in the frontal lobe but increases in the theta range in the temporal region (Murias et al. 2007). This finding suggests that there is overconnectivity in the frontal region but that the frontal lobe has weak functional connections with the rest of the cortex. EEG coherence studies in children with ASD report decreased coherences in delta, theta, and alpha ranges, suggesting underconnectivity (Coben et al. 2008; Isler et al. 2010).

MEG studies of connectivity have found mixed results, with some studies finding decreased connectivity in individuals with ASD (Muñoz-Yunta et al. 2008; Rojas et al. 2008) and another finding no differences between individuals with ASD and a control group in a simple evoked-response task (Coskun et al. 2009). Meanwhile, a MEG study examining coherence during an executive functioning task found decreased synchronization in the prefrontal cortex in the ASD group but increased synchronization in the parietal cortex (Velazquez et al. 2009). These findings provide support for abnormal functional connectivity with evidence supporting both a decreased or increased connectivity theory of ASD.

Imitation

The assessment of power in the mu frequency range has been used as a neurophysiological examination of imitation. The EEG mu rhythm is typically defined as brain activity oscillating in the 8–13-Hz frequency range recorded via centrally located scalp electrodes. When an individual is at rest, the underlying cell assemblies fire synchronously, but when an individual executes and, importantly, observes an action, the cell assemblies activate which attenuates the mu rhythm amplitude. As a result of this consistent

finding, it has been suggested that mu rhythm attenuation reflects activity of the mirror neuron system (Pineda 2005). Given the proposed role of the mirror neuron system in the neurobiology of imitation (Iacoboni 2009), examination of the EEG mu rhythm provides a noninvasive assessment of neurological activity playing a role in imitative ability. An EEG assessment imitation in adults with autism found that individuals with autism showed intact mu rhythm functioning (attenuation of the EEG mu rhythm) when executing movement but atypical activity (reduced attenuation) when observing actions compared to typical adults (Bernier et al. 2007). Further, imitation skills were associated with more attenuation when observing actions for both individuals with autism and typical individuals, suggesting that the neurological circuitry reflected in the mu rhythm play a significant role in imitative ability.

Attention and Disengagement

A study examining attention processing found that when task load was increased, children and adolescents with ASD showed increased early responses to unattended (visual) probes and failed to show normal reduction of processing to attended (auditory) probes. Additional studies have found that children with ASD demonstrate reduced attention ERP components when attending to targets in the periphery (Kemner et al. 1999; Townsend et al. 2001; Verbaten et al. 1991). These studies suggest that individuals with ASD may have subtle impairments in the integrative stages of attentional allocation.

Neurophysiological studies of attentional disengagement have found abnormalities of disengagement in adults with ASD (Kawakubo et al. 2007) and children with ASD (Kikuchi et al. 2010). In this study, typically developing children exhibited a larger saccade-related ERP components when viewing faces compared to children with ASD, whereas disengagement from objects did not differ between individuals with ASD and controls. These results support previous results of face processing deficits in ASD and suggest that disengagement from faces may require a higher level of cortical recruitment than disengagement from objects in individuals with ASD.

Auditory Processing

Neurophysiological methods provide insights into early lexical and semantic processing deficits observed in individuals with ASD. An auditory component (P450) was reduced in individuals with ASD and also was associated with increased EEG gamma power, which the authors suggested was indicative of abnormal inhibitory control (Orekhova et al. 2008). A study of brainstorm responses to speech syllables found that individuals with autism had deficient pitch tracking, suggesting subcortical abnormalities contributing to prosody-encoding deficits (Russo et al. 2008).

ERP studies have found abnormalities in neural processing of semantic information in children with ASD. Dunn and colleagues found that children with ASD failed to elicit an electrophysiological component (N400) indicative of detection of semantic incongruency (e.g., a mismatch) between animal and nonanimal words suggestive of semantic classification impairments (Dunn and Bates 2005; Dunn et al. 1999). Another ERP study aimed to examine if this deficit was limited to the verbal domain and found that high functioning children with ASD showed no electrophysiological index of the detection of semantic incongruence (i.e., no N400 effect) in response to words that mismatched the pictures; participants did show this N400 effect for nonverbal, environmental sounds. These results suggest a semantic abnormality specific to the verbal domain (McCleery et al. 2009). Other ERP studies report decreased component amplitude in response to repetitive speech, but not to repetitive nonspeech, and decreased orienting to novel tones in the sequence of speech sounds, but not in a sequence of tones (Whitehouse and Bishop 2008). These results suggest that inhibition occurs in individuals with ASD to repeated streams of speech.

MEG studies have also proved useful in understanding auditory and language processing difficulties in AS. A magnetoencephalography (MEG) study found an electrophysiological signature in detecting auditory processing deficits in children who have ASD and other language disorders (Roberts et al. 2008). In addition, MEG studies assessing auditory cortex functioning have found that children with ASD have reduced gamma

band power (Rojas et al. 2008) and abnormal left-hemispheric gamma oscillations (Wilson et al. 2007).

Executive Functioning

Neurophysiological studies have also uncovered underlying neural abnormalities to executive functioning deficits often observed in individuals with ASD such as perseverative responding, stereotyped repetitive behaviors, and an inability to accurately monitor ongoing behavior. Henderson et al. (2006) found that highly verbal children with ASD displayed reduced error-related negativity (ERN) amplitudes in response to an executive function task than control children, consistent with difficulties in self-monitoring ongoing behavior in social settings. A study examining response monitoring found that adults with ASD showed reduced error-related negativity and positivity amplitudes and reduced rostral anterior cingulate cortex (ACC) activation compared with controls and that reduced ACC activation was associated with increased social impairments and autism symptoms (Santesso et al. 2011). The authors suggest that the anterior cingulate cortex may be implicated in the social impairments observed in ASD. Another study examining error monitoring also found reduced ERN localized in the ACC (Sokhadze et al. 2010). Finally, an ERP study found a reduced error-related negativity and positivity to an auditory task, indicating an insensitivity to detect the possibility of errors (Vlamings et al. 2008). Together, these results suggest general impairment in self-monitoring and other executive functioning abilities underlying social and behavioral difficulties in ASD.

Reward Processing

Researchers have suggested that individuals with ASD have reduced social motivation such that they do not properly anticipate and appreciate the pleasure of social stimuli. Behavioral studies have also shown that children with ASD have difficulty learning stimulus-reward associations for both social and nonsocial rewards (Dawson et al. 1998). Event-related brain potential (ERP) studies aimed at assessing reward anticipation

(initiated by cue signals) and a potential rewarding outcome employed a modified go/no go paradigm. During this paradigm, a salient, motivating stimulus elicits a larger amplitude in the ERP component, P3. An ERP study of reward incentive found that children with ASD did not exhibit a bigger P3 to reward compared to nonreward stimuli, irrespective of reward type (social vs monetary) (Kohls et al. 2011). These results suggest that individuals with ASD have an atypical motivation-related brain response to reward cues that may be suggestive of a general reward processing deficit rather than social reward dysfunction. No behavioral differences were found in this study, suggesting that neurophysiological methods may be more sensitive than behavioral measures at identifying abnormal reward processing.

Amygdala Functioning

Atypical amygdala function has been implicated in the development and maintenance of emotional and social impairments in ASD. The amygdala and its interconnections with other brain regions play a crucial role in perceiving emotional stimuli, appraising novel situations, detecting danger, and modulating fear response. Amygdala function can be assessed via a fear conditioning paradigm known as fear potentiated startle (FPS). Thus far, findings fail to find differences in potentiated startle response in individuals with ASD compared to control groups (Bernier et al. 2005; Salmond et al. 2003), despite strong implications for amygdala dysfunction in the disorder.

psychology. Neuroscientists work at many levels of the nervous system from the molecular to the neural systems level, and they address many kinds of questions ranging across the molecular, cellular, developmental, structural, functional, evolutionary, computational, and medical aspects of the nervous system. The techniques used by neuroscientists have evolved rapidly, from molecular and cellular studies of individual nerve cells to imaging of sensory and motor tasks in the brain, to computational modeling of neural networks. These technological advances have revolutionized the study of neural systems and their development in the living, thinking, human brain.

Neuroscience

Kevin A. Pelphrey Harris
Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Synonyms

[Neural science](#); [Neurobiology](#)

Definition

Neuroscience is the scientific study of the nervous system and the ways in which the nervous system gives rise to behavior and cognition. Neuroscience is developed as a subfield or branch of biology. As such, the term neurobiology has often been used interchangeably with neuroscience. Neuroscience as a field has evolved as a highly interdisciplinary field or science of its own that incorporates techniques and concepts from many distinct fields outside of biology proper including chemistry, computer science, engineering, linguistics, genetics, mathematics, medicine (especially psychiatry), philosophy, physics, and

Neurotransmitter

George M. Anderson
Laboratory of Developmental Neurochemistry,
Yale Child Study Center, Yale University,
New Haven, CT, USA

Definition

A chemical released by neurons that is involved in the transmission of neural impulses or that affects

the transmission in some way. Neurotransmitters are typically contained in synaptic vesicles and upon neuronal stimulation are released at the terminals of neurons into the synapse or gap between neurons. They then diffuse rapidly across the synapse and interact with receptors on the postsynaptic neuron. Neurotransmitters can also bind to autoreceptors found on the releasing neuron and thereby modulate their own release and synthesis. Major classes of neurotransmitters include acetylcholine; the monoamines, including serotonin, dopamine, norepinephrine, and histamine; the amino acid neurotransmitters, including glutamate and GABA; the neuropeptides; and the gaseous transmitters including nitric oxide, carbon monoxide, and hydrogen sulfide.

Neurotypical

Danielle Perszyk
Yale Child Study Center, New Haven, CT, USA

Synonyms

Control; Normal; Typical; Typically developing

Definition

Description of a medically and psychologically healthy individual demonstrating a normative pattern of neurodevelopment. Typically used specifically in contrast with individuals experiencing an atypical developmental course, such as autism, and often used to describe the control group in clinical research. Its use varies from scientific publications (Cashin 2006) to tongue-in-cheek descriptions highlighting the subjective nature and valenced language often employed in research on social behavior (Larsen 2010).

New Zealand and Autism

Peter W. Dowrick¹ and Holly Smith²

¹University of Auckland, Auckland, New Zealand

²Psychology Department, University of Canterbury, Christchurch, New Zealand

Historical Background

The current autism picture in Aotearoa New Zealand is similar to that of other technologically developed countries in the Western hemisphere. That is, the identification of autism, especially high functioning autism, has skyrocketed in the last 15 years because resources and full enrolment in schools from age 5 have allowed identification to increase. (Aotearoa is the indigenous Maori name for NZ.)

The picture has not always been this way, as NZ did not follow the recognition of autism from

Leo Kanner (1943) or Hans Asperger (1991/1944) until the mid-1960s. At that time, child psychiatrist Mildred Creak visited New Zealand on her way to Perth Australia (Feinstein 2011). She had established the first (9-pt) behavioral observation checklist in London Hospital, and she brought current understanding of autism (and some clinical services) to NZ. This led to the setting up by families of a unit within the IHC (then the Society for Intellectually Handicapped Children).

From these beginnings, also in the 1960s, with international stimulation, New Zealander Marion Bruce founded the Autistic Association (Manson and Stace 2016), now known as Autism New Zealand, a nongovernmental organization with over 6,000 members – families and professionals, in many branches headquartered in Auckland (Autism New Zealand 2017). They provide parent training, supported employment, special tuition, some professional support, and information on “Autism Spectrum Disorders including Asperger’s Syndrome.” Currently they work with limited government funding and their waiting lists are long; for example, they are reluctant to recommend Discrete Trial Training because the waiting list is nearly 2 years (Autism New Zealand 2017). Another NGO, Altogether Autism, was established in 2007 by the Ministry of Health, as a spinoff from the Parent-to-Parent Network. It provides somewhere to go for families with unusual or extreme cases to seek support (Altogether Autism 2017).

The IHC has provided support for the full range of intellectual disabilities in children since 1949 (IHC 2017). It now supports thousands of children and adults. Historically, this support has included individuals with autism, but the contract ended in March 2017, with responsibility transferred to a relatively new provider of individualized supports Explore Specialist Advice (2017). IHC has been notable for its rejection by its founders of large institutions, and of all institutions since the 1950s, thanks to the dedication of Harold and Margaret Anyon, founders of IHC, whose son had an intellectual disability (New Zealand History 2017). In 1959, the NZ branch of the British Medical Association publicly opposed the use of large institutions for those

with intellectual disabilities. Consequently, the IHC received government funding to provide community-based services (New Zealand History 2017). Between 1980 and 2006, all major institutions were phased out.

Legal Issues, Mandates for Service

The Ministries of Health and Education have the possibly awkward joint responsibility for services and support for autism-related conditions. On the positive side, they have commissioned the development of the *New Zealand Autism Spectrum Disorder Guideline* (2008, revised in 2016), following the Curry Report (1998). This document (Ministry of Health 2016) provides evidence-based information concerning people “on the autism spectrum” for families and professionals. A process was set up for regular updates over time.

Since 2014, children and adults with ASD have been eligible for a full range of support services (Ministries of Health and Education 2016). Eligibility and subsequent access to state-funded services are determined by various work groups of the Ministry of Health. Currently, services are available (funded) only for children and adolescents with ASD and for adults who also have an intellectual disability. The recommendation that specialist diagnostic assessments be available for all ages has yet to be acted upon – see the NZ ASD Guideline (Ministry of Health 2016).

Overview of Current Treatments and Centers

Services in New Zealand are provided by the Ministries of Health and Education, related government agencies, and an evolving selection of NGOs. Since the 1980s, NZ government services in general have increasingly been “outsourced,” from the post office and telephone to the road works. Effective models have been difficult to establish, with many large agencies maintaining a monopoly with government control and restrictions on trade. Even so, special needs services for education and mental health have recently

developed considerably, even positively, except not being able to keep up with the demand.

The services required can be considered to fall into fall categories of (1) mental health and education; (2) age groups of preschool, school (ages 5–19), and adulthood including further education; and (3) high functioning versus intellectual disabilities in autism. The Ministry of Health website describes the “autism spectrum disorder” as a range of conditions including “autism and Asperger syndrome.” It notes ASD is thought to affect 1 in 100 New Zealanders; there has been no effort yet to make a systematic count. The website lists sources of support for autism as two other Ministries of (Education; Social Development) and at least seven nongovernment agencies: Autism NZ, Altogether Autism, IDEA Services (IHC), Kid’s Health, Cloud 9 Children’s Foundation, and the Werry Centre. Others are listed in the “[See Also](#)” section below.

The Ministry of Education offers diagnostic referrals for children including preschoolers, or young adults seeking higher education. Clusters of schools employ Resource Teachers for Learning and Behaviour (RTLBs) in school Years 1–10 (5–14 years olds) for children with serious behavioral needs (disabilities) and an extra mandate for Maori and Pasifika. They have struggled since 2000 to provide significant improvement in school performance for their caseload. Schools also have some, but limited, access to psychologists, speech and language therapists, physiotherapists, occupational therapists, and social workers (<http://rtlb.tki.org.nz/>). They also have some funding for teacher aides to improve inclusive schooling. There are limited enrolments in special schools and special classrooms.

Schools cooperate with NGOs who attempt outreach and the provision of services to families. These agencies typically get 10% or less of their funding from the government, relying on grants and charitable donations to make most services free to the public. For example, Autism NZ provides family support, individual training, and advocacy. Their mandate includes preschool, school-age, and adult individuals. For example, they may be the only ones offering training and personnel for supported employment. They are

the largest nongovernment agency specifically for autism in NZ with over 6,000 members and 17 branches. They work directly with families in collaboration with schools and other agencies. Explore Services is a relatively new agency, taking over from IDEA in 2014. They provide “behavior support” for over 4,000 people with disabilities and challenging behavior, nearly 50% with autism, having a mandate both broader and narrower than Autism NZ. They employ a large number of health professionals with sector experience, including a most significant number of psychologists.

Altogether Autism is emerging as a growing resource nationally, based in Hamilton. For example, in 2017 it staged a national conference which attracted a large number of outspoken “Autistics and Aspies,” as well as professionals and family members, and it has joined the Asia-Pacific Autism consortium. That is a recognition of Asia as the fastest growing region in the world, in many respects including the recognition and services for autism. The agency was established in 2007 by the Ministry of Health to provide high quality disability information and advice, especially around specific issues that have eluded others. For this they retain a panel of experts and part-time consultants. The Ongoing Resourcing Scheme has funding for those with the most extreme difficulties (1%). There are several other agencies providing advice and support for autism. These include the Special Education Early Intervention Service with extra support and preschool referrals, and the Children’s Autism Foundation, a charitable trust, providing advice for families with children up to the age of 21, plus other agencies noted elsewhere.

Overview of Research Directions

A modest but increasing amount of research on autism has been achieved in NZ. Based at the University of Auckland, the recently established Minds for Minds Research Network has the subtitle “Unlocking Autism Together” (Virues-Ortega et al. 2017). It includes a major thrust in genetic research and smaller studies in learning, neuropsychology, and speech and language. The

physiological studies, led by Russell Snell, are linking DNA to variations in autism and the functional connections between the stomach and the autistic brain (e.g., Arons et al. 2016). These are large studies, sometimes including dozens of authors, not only from NZ but California and other places.

Recent work is expanding with significant funding for the study of sleep problems in children with autism, following behavioral case studies (e.g., McLay et al. 2017). Significant “small-n” studies in learning, behavior, and speech and language are growing in number (e.g., Smith et al. 2014). These studies, which so far do not include adults, can be expected to generalize worldwide to children with autism and are not specific to NZ.

Overview of Training

Ongoing training of providers (teachers, health care professionals, and others)

Social Policy and Current Controversies

There are always too many controversies surrounding autism, from “something in the drinking water” to “genius unable to express itself.” Currently, they are overshadowed by vaccines as a cause – never mind that the NZ government has prohibited thimerosal. All agencies are outspokenly opposed to the view that Measles-Mumps-Rubella vaccines (free to everyone after the age of 12 months) can cause autism. Recently, the incidence of mumps has doubled and there have been outbreaks of measles, because the national rates of vaccination have been so low and a few individuals have brought these diseases from overseas. Such myths have long been debunked as fraudulent (e.g., Taylor et al. 1999) by Altogether Autism (March 2017) and others, but persist, spread by alarmists and even a popular film (Kohn 2016).

Many other treatments have drifted in from overseas and have minority followings. While

the majority of endorsed autism “treatments” are based in scientific research, historically some of the proposed causes of autism developed from less scientific methods. The theory of “refrigerator mothers” has gone. In the 1950s and 1960s, schizophrenia was often “diagnosed,” despite it usually being presented in late adolescence. Subsequent treatments with little or no empirical support include electric shock treatment (an attempt to stop self-injury), the use of D-lysergic acid diethylamide (LSD), elimination diets, sensory integration therapy, and testosterone treatment.

Training

Universities in NZ offer degree programs and coursework that contribute to professional training. The University of Auckland has an accredited Postgraduate Diploma in Applied Psychology that includes approaches to autism, emphasizing operant methods and some modeling/self-modeling. Canterbury and Victoria Universities are strong through Psychology or Education. To become a special educator or resource teacher requires an initial teaching qualification followed by a postgraduate diploma, available from Massey University campuses or distance education. The Ministries of Health and Education offer printed guidelines and substantial workshops for educators, therapists, and family members.

Other training programs specific to children with autism are mainly provided by various NGOs. For example, Altogether Autism provides a Professional Development Series as in-service training related to the autism spectrum. Autism NZ provides several substantial programs aimed at individuals with autism, educators, professionals, and parents, focused on understanding and practical strategies for quality of life and learning for those with autism. The programs educate on how to build independence, manage inappropriate behavior, and facilitate inclusion. Explore, the new government provider of autism services, is developing an array of training programs for families and professionals.

Definition

Next-generation sequencing (NGS) refers to DNA sequencing methods that have superseded the traditional method of Sanger DNA sequencing. In contrast to the Sanger method of chain termination followed by capillary electrophoresis, NGS technology typically uses sequencing by synthesis coupled with advanced methods to detect nucleotide incorporation. Importantly, NGS allows massive parallelization and efficient use of reagents, thereby drastically reducing cost and increasing throughput. These characteristics are essential for sequencing the many genomes and exomes required for sufficiently powered gene discovery studies in ASD and many other disorders. Over the last 10 years, the cost of sequencing has dropped 1,000,000-fold due to the use of NGS methods; however, Sanger sequencing, due to its high accuracy and independent methodology, is still used to confirm sequences called by NGS methods. In essence, NGS consists of three steps: (1) library preparation, (2) DNA amplification and array of clonal DNA clusters, and (3) massively parallel sequencing by alternating cycles of nucleotide addition and detection by various technologies, including fluorescent imaging by a camera or changes in pH measured by a semiconductor chip.

During library prep, DNA is fragmented and ligated to nonspecific adaptor sequences. Next, DNA amplification is achieved via several methods (such as PCR, using adaptor-specific primers), and,

usually, clusters of clonal DNA are arranged on the sequencing substrate in an array. This process allows for sequencing in a massively parallel fashion by pairing the sequencing signal from a given stretch of DNA with a specific, constant location on the sequencing chip. Since there are millions of clusters arrayed across each sequencing chip, the sequence of millions of fragments is simultaneously determined in parallel (Shendure and Ji 2008).

During sequencing by synthesis, primed templates are serially extended by incorporation of nucleotides, which is generally detected by one of the two methods: fluorescence imaging or voltage monitoring. Fluorescence imaging uses fluorescently marked nucleotides, with a different color of fluorescence for each of the four nucleotides (A, G, C, or T). A digital camera records the color of each cluster of clonal DNA and uses this to determine the base present. The fluorescence is then removed and the next cycle of sequencing begins. Thus, the sequence of nucleotides composing a particular fragment of DNA can be recorded by the color pattern of nucleotide incorporation. Data collection can also be achieved by detecting the changes in pH (via changes in electrical potential) produced by the incorporation of a nucleotide into a strand of DNA. The repeated, sequential addition of the four nucleotides allows for the identification of which base comes next in the sequence, according to which addition produces a decrease in pH (Rothberg et al. 2011).

The data produced by all types of NGS is in the form of short (10–1000 base pair) reads, depending on the NGS technology, instrument, and settings used. The final step, in order to interpret the sequence, necessitates the alignment of each read to the human genome, a process that requires considerable computing power. Each technology has both pros and cons regarding cost, accuracy, speed, and versatility and varies in usage across different research and clinical settings.

[Alpha-4 beta-2 nicotinic agonists](#); [Alpha-7 nicotinic agonists](#)

Definition

Nicotine binds to nicotinic receptors throughout the brain and the body. Acetylcholine is the naturally occurring molecule that also binds to these receptors. Transdermal nicotine is given to smokers to prevent withdrawal symptoms. Some studies have suggested alterations in nicotine receptors and acetylcholine levels in individuals with autism spectrum disorder. Nicotine has been found to reduce symptoms of aggression in individuals with Alzheimer's disease and schizophrenia in early trials. Nicotine also has anti-aggressive effects in mouse models. A single case report describes improvement in aggression in an adolescent with autism spectrum disorder following nicotine administration (Van Schalkwyk et al. 2015).

Definition

Nigeria, also known as the Federal Republic of Nigeria, is a country located in the West African subregion bordered by the Republic of Benin in

the West, Chad and Cameroon in the East, and the Niger Republic in the North. The Nigerian coast in the South lies on the Gulf of Guinea on the Atlantic Ocean. Nigeria is a country with over two hundred and fifty ethnic groups, but the three major traditional groups are the Hausa-Fulani, the Yoruba, and the Igbo. Geopolitically, the country consists of 6 regions or zones and 36 states and a Federal Capital Territory located in Abuja.

There is growing momentum recognizing Autism Spectrum Disorder (ASD) globally and advocating for the needs and rights of children in low and middle income countries (LMICs) (Munir et al. 2016). In 2010, there were approximately 52 million people living with ASD worldwide (Elsabbagh et al. 2012; Baxter et al. 2015). Whereas in the United States, ASD is recognized to affect 1 in every 68 children (1 in 42 boys and 1 in 189 girls) (Christensen et al. 2016), the data on prevalence of ASD in LMICs is limited (Bakare et al. 2019). Most research into the epidemiology, causes, clinical presentations, diagnosis, and treatment of ASD is based on studies conducted in high-income countries (HICs). This has led to a misperception that ASD is more prevalent in HICs versus LMICs. For example, while only 20% of the world's current population resides in HICs, 86.5% of all reported cases of ASD have been in HICs (Elsabbagh et al. 2012; Population Reference Bureau 2015). Nigeria is the most populous country in sub-Saharan African with an estimated population of over 180 million people, with children under the age of 15 years accounting for about 35 percent of this population. Barring geographic environmental and genetic variation, there is no reason to expect that prevalence of ASD in LMICs will be lower than that consistently reported in HICs. There is a need to strengthen national capacities in Nigeria in ASD and neurodevelopmental disorders. This chapter will outline the current knowledge of ASD in Nigeria and highlight challenges currently facing the communities as they aim to advocate for services for persons with ASD across the lifespan.

Historical Background

Origins

Following Leo Kanner's pioneering work on ASD dating back to 1943 (Kanner 1943), the first documented cases of ASD in Nigeria were in fact noted in 1972 by Longe and Asuni in a scientific paper read at the Third Pan African Psychiatric Conference in Khartoum, Sudan, where they reported four cases of Infantile Autism among Nigerian children (Longe and Asuni 1972). Subsequently in 1978, Victor Lotter screened children with intellectual disabilities in nine major cities of six African countries that included Ghana, Nigeria, Kenya, Zimbabwe, Zambia, and South Africa. Nine out of 1,312 children with intellectual disabilities studied in these countries met the eligibility criteria to be classified as having ASD, a rate which was 1 in 145 (Lotter 1978). Onuora in 1993 also reported another case of ASD in Nigeria in a case report published in Nigerian Journal of Psychiatry (Onuora 1993). Therefore, with these exceptions, in the years prior to the turn of the twenty-first century, cases of ASD were only sparsely reported in Nigeria or any other sub-Saharan African country.

Emergence of Interest in Knowledge and Awareness

Focus on increasing knowledge and awareness about ASD in Nigeria was heralded by the pioneer work of African Network for the Prevention and Protection against Child Abuse and Neglect (ANPPCAN) Nigeria Chapter in 2007. ANPPCAN Nigeria Chapter in collaboration with the World Bank carried out a survey to ascertain the level of knowledge and awareness of healthcare workers and the general public in Enugu State on ASD in Southeastern Nigeria and implemented a project aimed at increasing the level of knowledge and awareness about ASD through public enlightenment, stake holders' meeting, and a radio program. The report of the survey showed that there is a very low level of knowledge about ASD among the general public and a low to average level of knowledge and

awareness about ASD among various categories of healthcare workers, with relatively highest level of knowledge noted among healthcare workers working in Psychiatric Facilities (ANPPCAN 2007; Bakare et al. 2008). The heightened recognition of ASD can also be attributed to knowledge of elevated prevalence figures recorded in the HICs over the previous two decades among number of investigators in sub-Saharan African region (Fombonne 2003; Bakare et al. 2008).

Since 2007, there has been an increase in the number of research papers on knowledge assessment among Nigerian population, highlighting the clinical characteristics of children with ASD. These have included case reports describing associated co-morbidities and socio-cultural context of ASD among Nigerian children, as well as pockets of prevalence studies among clinical and specialized populations (Bakare and Ikegwuonu 2008; Bakare et al. 2009a; b, 2011a, b, 2012, 2014, 2015, 2016; Igwe et al. 2010, 2011; Bakare and Munir 2011a, b, c; Bello-Mojeed et al. 2011, 2013, 2016, 2017; Bello-Mojeed and Bakare 2013; Ezegwui et al. 2014; Lagunju et al. 2014; Esegibe et al. 2015; Izuwah et al. 2016; Chinawa et al. 2016; Oshodi et al. 2017).

From a public health perspective, the reported overrepresentation of nonverbal cases in clinical populations (Bakare and Munir 2011a) and late identification of ASD (Bello-Mojeed et al. 2011) have emphasized the urgent need for shifting research and public health focus from infectious to Non-Communicable Disease (NCD) priorities, with prioritization of early identification of neurodevelopmental disorders and early interventions for them (Bakare and Munir 2011b; c; Bakare et al. 2014). Unfortunately, the studies on Nigerian adults with ASD have so far been lacking.

Legislative Guidance

At the moment, there is no legislation in Nigeria directed at guiding or mandating services for individuals with ASD specifically. However, the Child Rights Act provides for the rights of children to education, health, and other social

needs. Though this law has been poorly implemented across the nation, Nigeria adopted the Child Rights Act in 2003. The law incorporates the principles of the United Nations Convention on the Rights of the Child, providing a framework for preventing and responding to violence abuse, neglect, and exploitation of children. To date, only 23 of the 36 states in Nigeria have adopted the law, with predominantly Northern Nigerian States Legislative Assemblies yet to accept it (UNICEF Nigeria 2017). In the Nigerian States where the law has been adopted, it has also been poorly implemented, as many cases of violation of children's rights go unreported and unpunished because of reluctance in challenging such cases in courts of law (UNICEF Nigeria 2017; Bakare et al. 2009a).

While the Child Rights Act may address the social and policy needs of children with ASD, adults with ASD in Nigeria may have some relief in the nearest future because of the recent passage and accent to Nigeria Disability Law that is meant to protect the rights of persons with serious neurodevelopmental disabilities (Pulse.ng 2019). The rights of adult with ASD ideally would be taken care of by the Nigeria Disability Law if it is subjected repeatedly to judicial tests to reinforce acceptance of the Law by the general populace. Negative cultural and social issues are among the factors hindering the full implementation of Child Rights Act and may affect acceptance of Nigeria Disability Bill as well. A lot of public health education is still needed to effect change in perception and behavior towards people with disabilities in Nigeria.

Current Treatment and Centers

Treatment and management of any disease condition is often influenced by health behavior of the people, which in turn is a function of attributed etiological explanations. Close to 50% of Nigerian populace, especially in rural communities still attributed the etiology of ASD to spiritual causes (Bakare and Munir 2011a). Hence, the tendency for parents and relatives of children with ASD to seek succor from traditional and religious healers as first point of contact

before seeking help from orthodox practitioners (Bakare and Munir 2011a).

Traditional practice and interventions for ASD in Nigeria are available at Psychiatry and Pediatric facilities of National and States Teaching Hospitals, Specialized Psychiatric Hospitals, and General Hospitals spread across the 36 States of Nigeria and Federal Capital territory in Abuja. Pockets of privately owned Hospitals spread across the country and also provide traditional interventions. Treatments offered in these settings focus largely at alleviating associated problem behaviors and treating medical co-morbidities like seizure disorders and attention deficit hyperactivity disorder symptoms, among other disruptive or injurious behaviors. In view of the fact that majority of cases of ASD presenting to such orthodox practices have tendency for late diagnosis, arising from late or delayed identification (Bakare and Munir 2011a), and the fact that period of onset of ASD in Nigeria and most sub-Saharan African settings coincide with period of neurological infections and complications like cerebral malaria, meningitis, kernicterus among others, cases of ASD seen in Nigerian hospitals and clinics are often in the severe end of the autism spectrum with attendant neurological problems presenting as medical co-morbidities, intellectual disability, and lack of expressive language ability (Bakare and Munir 2011c).

Treatment Centers available in Nigeria that the patients and their relatives present to can be categorized as follows:

Traditional Healers: Based across the country, especially in the rural communities, the traditional healers provide a form of psychological support or comfort that compound the problem of early identification and intervention.

Religious Healers: These include mostly Alfas and Pentecostal Churches that often promise spiritual healing and exorcism. Such centers provide support and reassurance, and false hope, resulting in delaying presentation in health settings in most cases.

Private Homes/Schools and Non-Governmental Organizations (NGOs): Most of these private

homes and schools as well as NGOs found across the country often do not provide services specific to ASD. Most house orphaned and vulnerable children with ASD and intellectual disability. Many provide stimulating play environments and some form of remedial education for the children. The practice of these private homes and schools and the NGOs are not properly regulated, and the local standard of care or interventions they offer may not meet ethical and scientific standards to be considered evidence-base. However, they provide a ray of hope in an environment where there is little or no hope. The services are often expensive and mostly unaffordable for average parents.

Orthodox (Traditional) Medical Practices: These consist of settings like teaching hospitals, specialized psychiatric hospitals, general hospitals, and private hospitals that offer services to children with neurodevelopmental disorders. These practices also provide limited psychological support and address associated problem behaviors and medical co-morbidities.

The core of treatment which is special education that focuses on social stimulation, language development (speech therapy), occupational and physical therapies, and community social inclusion programs are largely lacking in most of these centers. This is an area where future social policies and legislations need to be targeted in the future. Most educational settings in Nigeria are normal main-stream schools designed for normally developing children. Most special schools available, which are quite few and exorbitant in costs, are privately owned. Future direction need to enact a legislation to incorporate special education facilities into normal main-stream schools. This would promote social stimulation for Nigerian children with ASD and promote community inclusion and therefore reduce stigma.

Overview of Research Direction

There is no established or nationally adopted research direction on ASD in Nigeria. However,

suggested research direction based on the present state of ASD in Nigeria should include:

1. Defining the magnitude of the problem of ASD, and needs assessment of affected individuals through a well-implemented nationwide epidemiological study, augmented with genetic and environmental studies.
2. Administrative and research capacity development effort in terms of training for healthcare personnel, promoting human resource development in the area of interventions for ASD and other developmental disability.
3. Establishment of Special Education Departments that should be incorporated into normal mainstream schools to promote social stimulation and community inclusion to reduce stigma. This process would be better enhanced by legislation and policy formulation.
4. Full implementation of existing legislations like Child Rights Act and Nigeria Disability Law. These would promote educational and employment opportunities for people with various disabilities, including ASD. Social policy formulation should also address financial aspect of healthcare and special education provision for individuals with developmental disability since this is not presently covered under the Nigeria National Health Insurance Scheme (NHIS) or any existing social policies.
5. Lastly, research direction should focus on massive public health education to positively influence help seeking behavior for children with ASD and other neurodevelopmental delay, which often leads to late diagnosis and interventions (Bakare et al. 2016).

Social Policies and Current Controversies

Despite the adoption of Child rights Acts in year 2003 that promised equal opportunities to every Nigerian child, the full implementation has experienced clog wheel because not all the Nigerian States, in particular Northern and Southern, have adopted it and those States that have adopted it has had its implementation hindered by a number of political, cultural, and social factors. Many children with ASD and other neurodevelopmental

disabilities are therefore still being locked up in the house and have been prevented by the parents and their relatives from accessing any form of intervention. This is largely because of common derogatory comments and associated stigma of having those children that parents experienced. In addition, health insurance is not available for most parents and where available it does not cover cases like ASD and other developmental disabilities. This exposed parents to out-of-pocket huge cost of care for their children with ASD and other developmental disabilities. So in the cases of ASD in Nigeria, a mixture of stigma and financial burden of care have denied many individuals with ASD the opportunity of any form of intervention, either medical or special education services despite the availability of law that promised equal opportunities for every Nigerian child.

Adults with ASD and intellectual disability are also denied access to their rights. Many lack employment opportunities despite being qualified to take available job spaces due to stigma and discrimination. Unlike the children that have the advantage of Child Rights Act, the Nigeria Disability Law is just freshly enacted and has not gone through the rigor of judicial tests to assess its acceptance by the Nigerian public population.

The factors of poverty and ignorance that promote the culture of wandering and begging children in form of Almajiri system of Islamic education mainly in the Northern Nigeria also promote the culture of labeling children with any form of mental illness or intellectual disability in the southern Nigeria witches, leading to further violation of their rights and other privileges that the Child Rights Act promised every Nigerian Child (Stepping Stones Nigeria 2010; AbdulQadir and Chiranchi 2017).

Noncontingent Reinforcement (NCI)

Anna M. Krasno

The Gevirtz School, UC Santa Barbara Koegel Autism Center, Santa Barbara, CA, USA

Definition

Noncontingent reinforcement is the use of positive reinforcement that is not related to the occurrence of a target behavior. It involves delivering reinforcement on a fixed-time schedule independent of whether the individual exhibits the target behavior during the interval. In other words, the individual's behavior does not influence whether or not reinforcement is provided. For example, noncontingent reinforcement can be used with a child with autism who exhibits disruptive behavior in the classroom for the function of gaining attention from the teacher. The teacher could implement a noncontingent fixed-time schedule of reinforcement where she gives the student attention at fixed times throughout the day. Since he is receiving the attention throughout the day, this results in a decrease of disruptive behavior. Noncontingent reinforcement weakens the contingency between the target response (disruptive behavior) and the reinforcement delivery. If extinction is used at the same time, this means that no connection is made between the target response and the reinforcement and the behavior decreases.

Nonparametric Statistics

Daniel Campbell
Yale Child Study Center, Yale University, New Haven, CT, USA

Synonyms

Distribution-free statistics

Definition

Nonparametric statistics encompasses the statistical methods that do not make any assumptions about

the underlying distribution of data. It can be contrasted with *parametric statistics*, which makes explicit assumptions about the distribution of observed data and which uses the data to estimate *parameters* of that distribution. For example, it is common to assume that data is drawn from a normal distribution with unknown parameters μ (mean) and σ^2 (variance); a parametric approach would estimate μ and σ by the sample mean and the sample standard deviation, respectively. Nonparametric statistics, on the other hand, would not assume the data is normally distributed *a priori*, and instead would estimate the shape of the distribution itself.

There are two main types of nonparametric methods in statistics: methods that attempt to discover the unknown underlying distribution of the data, and methods that make statistical inferences without regard to any underlying distribution. Methods of the first type include the histogram, and kernel methods such as kernel density estimation. Methods of the second type include hypothesis tests based on the rank ordering of the data rather than the actual data values. Frequently used nonparametric tests include the Wilcoxon signed rank test, the Kruskal-Wallis test, and Spearman's and Kendall's rank-correlation coefficients.

Nonstandard Assessment

Louise Spear-Swerling
Southern Connecticut State University, New Haven, CT, USA

Definition

A *nonstandard assessment* is one that does not rely on a standardized test, often because

the student being evaluated does not fit the normative sample for the test. For example, if a student is an English language learner, ideally he or she should be assessed using a standardized test developed and normed on a population speaking the same native language as the student. However, for some languages, such tests may simply not be available. In this situation, an examiner might need to rely primarily on nonstandard assessment procedures such as observations of the student's language use in multiple settings and information from the family about the student's past language development and current language functioning.

The term *nonstandard assessment* also is sometimes used to describe accommodations of standard testing conditions for students with disabilities; these nonstandard assessment accommodations are intended to “level the playing field” for the student without altering the basic nature, reliability, or validity of the test. For instance, if an examiner wanted to administer a written test of science content knowledge to a student with very limited reading skills, then a nonstandard assessment involving reading the test items aloud and having the student give a verbal response would usually be acceptable; however, if the standardized test was intended to measure reading fluency, then the same nonstandard assessment would be inappropriate because the nonstandard assessment would not measure the student's reading fluency. As another example, a relatively lengthy test administration might be broken into several shorter testing segments for a student with an autism spectrum disorder in order to help maintain the student's consistent attention during testing. Although nonstandard assessments can provide useful information, they should be implemented and interpreted with caution.

Nonsymbolic Communication

► [Gestures](#)

Nonverbal Communication

Andrea McDuffie

MIND Institute University of California-Davis,
Sacramento, CA, USA

Definition

There are children with autism who may be considered nonverbal, that is, children who use very few spoken words on a daily basis or for whom spoken language is not their primary means of communication. Some children are young and have not yet developed spoken language skills. These young children would be considered preverbal. Other children or older individuals, who are above the age of 5 years, who have not developed functional spoken language skills can be considered nonverbal. Development of the ability to use nonprompted (i.e., spontaneous) spoken language in a flexible manner (i.e., across many contexts) prior to age 6 is known to predict positive long-term outcomes for individuals with autism; this ability is sometimes termed “useful speech.” Thus, individuals with autism who fail to develop useful speech during the preschool years may require other approaches to allow them to achieve the ability to communicate functionally by other means. Communication systems designed to be used by individuals without

functional spoken language skills are termed “augmentative and alternative communication” (AAC) systems; these systems include the use of gestures, eye gaze, body postures, sign language, photographs, printed words, objects, and symbols as the means of conveying meaning. In fact, research has shown that the use of an AAC system can support the development of spoken language in individuals who are considered nonverbal. Research is now underway to identify those children who may not respond well to behavioral interventions focusing on the development of spoken language and who may need earlier access to AAC systems.

The picture exchange communication system (PECS) is an example of an AAC system that can be used with children with autism who are nonverbal or minimally verbal. In the PECS approach, children use a picture exchange with a communicative partner to access desired materials. The partner responds to the child’s communication act (i.e., giving the picture) by putting the child’s communicative message into words. The use of PECS can be incorporated into a variety of intervention approaches (e.g., prelinguistic milieu teaching) to provide the means by which a child can produce a communication act.

Nonverbal Intelligence

Emily S. Kuschner

Center for Autism Spectrum Disorders, Division of Neuropsychology, Children’s National Medical Center, Washington, DC, USA

Definition

Nonverbal intelligence describes thinking skills and problem-solving abilities that do not fundamentally require verbal language production and comprehension. This type of intelligence involves manipulating or problem solving about visual information and may vary in the amount of internalized, abstract, or conceptual reasoning and motor skills that are required to complete a task. Nonverbal intelligence is often closely linked with the Performance IQ domain of intellectual ability tests that evaluates nonverbal abilities, a domain which is often viewed in comparison to the Verbal IQ domain.

Historical Background

The earliest intelligence tests developed in the mid- to late-1800s primarily measured sensory and motor abilities rather than conceptual or language abilities. However, the introduction of the 1905 Binet-Simon Scale and factor analytic theories of intelligence brought a wave of new perspectives on intelligence testing, separating out visual processing/reasoning/perception as unique components of intelligence. Historically, nonverbal IQ assessments were developed by the US military in World War I with the goal of assessing recruits who had impaired verbal/language abilities (e.g., illiterate, less proficient with English).

Nonverbal intelligence often plays a key role in understanding cognition and intellectual abilities for individuals with autism spectrum disorder (ASD). An uneven pattern of cognitive strengths and weaknesses in individuals with ASD has been documented as far back as Kanner's early descriptions of the disorder. His observations of attention to detail at the expense of global meaning, and a wealth of subsequent research findings in the field, led to the belief that enhanced nonverbal abilities may be a core feature for all individuals with ASD. It is now understood that these nonverbal abilities vary based on age, language level, overall level of functioning, and diagnosis, but are still crucial to the understanding of cognitive profiles in many individuals with ASD.

Current Knowledge

Assessment of Nonverbal Intelligence

Measurement of nonverbal intelligence serves two key functions: First, tests of nonverbal intelligence offer an assessment of nonverbal abilities, such as disembedding, visual sequencing, and pattern recognition skills. Some tests are designed to solely assess nonverbal abilities (e.g., Leiter International Performance Scale-Revised, Universal Nonverbal Intelligence Test), while others offer index or composite scores for nonverbal skills alongside global scores for verbal skills (e.g., Perceptual Reasoning Index on the Wechsler Scale for Children, fourth edition; Nonverbal Cluster on the Differential Ability Scales). In

addition to assessing nonverbal abilities, nonverbal tests of intelligence can provide a mechanism for quantifying intellectual ability in individuals without spoken language or who have very impaired expressive and receptive language skills.

Intelligence tests vary in the extent to which they meet each of these purposes. For example, the Performance IQ (PIQ) subtests on the Wechsler scales measure non-language visual reasoning skills but provide instructions verbally. In contrast, on the Leiter International Performance Scale-Revised (Leiter-R) and the Test of Nonverbal Intelligence, Fourth Edition (TONI-4), all item prompts are administered with gestures and facial expressions, and individuals respond by pointing to pictures or by moving cards/shapes. These tests of intelligence that are nonverbal offer the advantage of removing verbal language demands from both administration and response. However, it should be noted that internalized language often still assists performance on nonverbal intelligence tests. For instance, when completing a sequencing or pattern recognition task, performance is often improved by orally or internally labeling the components of the sequence/pattern (e.g., car, plane, car, plane). In other words, nonverbal tests may still be measuring aspects of verbal abilities.

Nonverbal Intelligence in ASD

Assessment of intellectual ability can be very complicated for individuals with ASD given the uneven pattern of abilities across domains of functioning. For individuals with ASD, a Full Scale IQ (FSIQ) score can be misrepresentative since it will average across peaks and troughs in functioning. There is the risk that interpretations of these average scores will dampen the presence of particular areas of strength and mask the significance or impact of areas of impairment.

It has been consistently documented that individuals with ASD have an uneven or spiky profile of intellectual and cognitive abilities, with nonverbal abilities often shown to be stronger than verbal abilities. This pattern has most frequently been discussed as a characteristic profile of scores across domains on the Wechsler intelligence tests, with PIQ exceeding Verbal IQ (VIQ). Peaks in PIQ performance are evident on the Block Design and Matrix Reasoning subtests that tap into

visuoperceptual processing. In Block Design, a set of colored blocks is used to create a design presented in a picture (i.e., form a “whole” from its “parts”), and Matrix Reasoning requires the identification of missing parts of pictures. In contrast, a relative weakness on the Wechsler scales is consistently demonstrated on the Comprehension subtest of the VIQ index, a task requiring the integration of social knowledge and conventions (e.g., “What is the thing to do if you find an envelope in the street that is sealed, addressed, and has a new stamp on it?”). It should be noted that this is *not* the typical profile of individuals who meet the diagnostic criteria for Asperger’s disorder. This group has more frequently demonstrated high verbal IQ compared to lower performance IQ.

Valid assessment of intellectual functioning, and consideration of nonverbal intelligence, also plays an important role in ASD research. A measure of intellectual functioning is often needed to characterize the group of individuals with ASD who are participating in the study (e.g., Are the individuals with ASD of average, high, or low functioning abilities?). In addition, a group of individuals with ASD is often matched to another group of individuals (e.g., typically developing controls, individuals with another non-ASD developmental disorder) on a global measure of intellectual ability so that the two groups can be compared on a more specific cognitive ability or construct. The unevenness among cognitive abilities leads to difficult decisions regarding what type of test to use for matching across individuals or groups (e.g., Match based on the highest strength? The lowest weakness? An average across all skills?). This is such a complicated question that an entire issue of the *Journal of Autism and Developmental Disorders* (Vol. 34, No. 1) was devoted to these questions.

Variability Within Nonverbal Intelligence in ASD: A Nonverbal Perceptual Strength

Although nonverbal intelligence is often globally higher than verbal intelligence for individuals with ASD on molar tests, such as PIQ, there is variability among nonverbal abilities. Relative weaknesses are evident in nonverbal conceptual

tasks that require some abstraction of ideas (e.g., recognizing the sequence or pattern of a set of items, identifying the semantic relationship among the items). In contrast, and as described above, strengths in nonverbal intelligence are generally seen in nonverbal tasks that are perceptually demanding (e.g., the Block Design subtest, puzzles). More specifically, individuals with ASD are particularly good at disembedding details from the global elements or gestalt of stimuli and the world around them. This detail-focused processing style has been observed anecdotally by families and clinicians, and has been extensively explored in research studies. In addition to Kanner’s early descriptions, parents of individuals with ASD have often described their children’s uncanny ability to notice single books out of place on bookshelves, or complete puzzles with the pieces turned over. In empirical research, this processing style has been examined with a wide variety of tasks, including the Embedded Figures Test and hierarchical letter tasks. The Embedded Figures Test involves identifying a simple shape (e.g., a triangle) embedded in a complex picture (e.g., a baby carriage), while the hierarchical letter test requires attending to the detailed “local” aspects of a stimulus versus the gestalt or “global” aspects (e.g., a large A letter made up of little S letters). The general theme across these tasks is that individuals with ASD are able to process the detailed or local level of stimuli more accurately and/or efficiently than the global level. Researchers have theorized that these abilities may be a result of an enhanced ability to perceive details and ignore the global gestalt. Alternatively, these strengths may result from the inability (or reduced ability) to integrate whole and maintain the precedence of global features. Regardless of the mechanism, this area of research has consistently highlighted an area of strength for individuals with ASD, and has been conceptualized as a cognitive style rather than a cognitive deficit. Although there is some disagreement regarding how pervasive this detail-focused processing style is across individuals with ASD of different levels of functioning and subtypes, weak central coherence theory has sought to employ this perceptual bias in explaining other core features of ASD.

Future Directions

A clear understanding of nonverbal intelligence has allowed clinicians and researchers to capture areas of strength for individuals with ASD that might not otherwise be evident in verbally based measures of intellectual ability. However, the discrepancy between nonverbal and verbal abilities leads to the dilemma of what is “true” intelligence for individuals with ASD, and whether this is even possible to identify given wide variability within the population. For example, individuals with an Asperger syndrome diagnosis often contrast other individuals on the spectrum and demonstrate better verbal abilities and relatively lower nonverbal intelligence. With the anticipated change in DSM-V diagnostic criteria for ASD and the merging of all diagnoses into one ASD spectrum category, there will be added heterogeneity in cognitive profiles and further difficulty with capturing “true” intelligence for individuals with ASD.

Finally, intelligence is used as a predictor of outcome, and for some individuals with ASD, nonverbal and verbal intelligence scores would predict two very different trajectories for the same individual: (1) Do higher nonverbal IQ scores represent true potential when unburdened of verbal language? (2) Do these higher scores represent splinter skills that do not efficiently or effectively translate to other areas of functioning? Future research on the predictive abilities of nonverbal intelligence will be needed to provide clear answers to these questions.

Nonverbal Learning Disabilities (NLD), Second Edition

Yu Han
Neuroscience, University of Vermont,
Burlington, VT, USA

Synonyms

Developmental right-hemisphere syndrome; Nonverbal learning disorder; Social-emotional learning disability

Short Description of Definition

Nonverbal learning disability (NLD) is a neurobehavioral disorder that impacts a person's intelligence due to dysfunctions of the brain. NLD is a developmental disorder which constrains a child's linguistic performance in the nonverbal domain. While an individual with NLD shows deficits in understanding nonlinguistic signs, he/she can be highly functional in verbal communications. Other neuropsychological disorders related to NLD can impact a child's abilities to perform in academic, social/emotional, and vocational areas (Palombo 2006). A critical challenge for an individual with NLD is social interaction due to the lack of visual processing abilities such as recognizing facial expressions and lack of spatial perception. NLD is not apparent at a very young age, such as preschool age, although the inability to understand nonverbal signs significantly manifests at the age when children begin to understand social interaction through engagement in verbal conversation (Thompson 1996). NLD does not necessarily constrain academic skills, but impairs mainly social interactions with characteristics similar to what was previously identified as Asperger's syndrome, now part of Autism Spectrum Disorder (ASD), and pragmatic language impairment (PLI).

Categorization

Nonverbal learning disorder was first identified by Doris Johnson and Helmer Myklebust in 1967 as a subtype of learning disability. Based on research by Rourke et al. (1989), this class of learning disability is organized into two categories: phonological processing disorder and nonverbal learning disorder (p. 169). Typically, people with learning disabilities fail to perform at age level and exhibit difficulty in rote-verbal learning and in phonological processing. Unlike children with general learning disabilities, children with NLD demonstrate significantly higher verbal IQ than performance IQ. For example, children with NLD show primary impairments in visual processing, tactile perception, complex psychomotor

skills, fine motor skills, and manipulation of materials (Rourke 1989). Accordingly, they need significant support in adapting to changes, in generalizing what they have learned, and in following instructions with multiple steps.

There is no consensus on the cluster of learning disabilities that comprises NLD. Accurate procedures to diagnose children with NLD are not yet available as there have been multiple changes in classification. The American psychiatric association (APA) uses the diagnostic and statistical manual of mental disorder (DSM) to produce an accurate diagnosis within various mental disability categories (APA 2000). NLD was not included in the DSM-IV or in the current revision of the DSM-5 (APA 2013). Moreover, many symptoms of NLD are similar to those of ASD and PLI. The differences among these three disorders have not been clearly defined. It has been proposed that NLD may be a disorder on the “borderlands of autism” (Bishop 1989, p. 107). Children with ASD, who perform well in cognitive and linguistic areas, have features in common with both NLD and PLI. PLI is also considered to be a social communication disorder, meaning that children with PLI have difficulty using language appropriately in social situations. Overall, NLD, ASD, and PLI have overlapping, but not identical, symptoms. For example, an individual diagnosed with NLD will show some of the features of PLI, but the reverse may not be true (Bishop and Norbury 2002). The overlap of symptoms among these three learning disorders involves patterns of behavior in a social context. There is yet no evidence of restricted or repetitive patterns of behavior that clearly distinguishes the disorders.

The following is a set of criteria used to identify NLD (Rourke et al. 2002):

1. Bilateral deficits in tactile perception, usually more marked on left side of the body. Simple tactile perception may reach normal levels as the child ages, but interpreting complex tactile stimulation remains impaired.
2. Bilateral deficits in psychomotor coordination, usually more marked on the left side of

the body. Simple, repetitive motor skills may reach normal levels with age, but complex motor skills remain impaired or worsen relative to age norms.

3. Extremely impaired visual-spatial-organizational abilities. Simple visual discrimination can reach normal levels with age, particularly when stimuli are simple. Compared to age norms, complex visual-spatial-organizational abilities worsen with advancing years.
4. Substantial difficulty in dealing with novel or complex information or situations. A strong tendency to rely on rote, memorized reactions, approaches, and responses (often inappropriate for the situation), and failure to learn or adjust responses according to informational feedback. Also, frequent use of verbal responses in spite of the requirements of the novel situation. These tendencies remain or worsen with age.
5. Notable impairments in nonverbal problem solving, concept formation, and hypothesis testing.
6. Distorted sense of time. Estimating elapsed time over an interval and estimating time of day are both notable impairments.
7. Well-developed rote verbal abilities (e.g., single-word reading and spelling), frequently superior to age norms, in the context of notable poor reading comprehension abilities (particularly so in older children).
8. High verbosity that is rote and repetitive, with content disorders of language and deficits in functional/pragmatic aspects of language.
9. Substantial deficits in mechanical arithmetic and reading comprehension relative to strengths in single-word reading and spelling.
10. Extreme deficits in social perception, judgment, and interaction, often leading to eventual social isolation/withdrawal. Easily overwhelmed in novel situations, with a marked tendency toward extreme anxiety, even panic in such situations. High likelihood of developing internalized forms of psychopathology (e.g., depression) in later childhood and adolescence.

Epidemiology

Nonverbal learning disorder (NLD) is diagnosed less frequently than other language-based learning disorders (e.g., reading and written expression disorder). While approximately 10% of the population has been diagnosed with having a learning disability, only 0.1–1.0% of the population has been found to have NLD. NLD has been diagnosed equally in female and male populations (Thompson 1996). Moreover, based on social behavioral problems, children with NLD also show some features of attention deficit hyperactivity disorder (ADHD) and are easily misdiagnosed as having ADHD (Antshel and Khan 2008). Educators often define NLD as a language-based learning disability based on academic and cognitive assessments. Thus, the data regarding NLD are unclear and, as a result, NLD is often misdiagnosed as other types of learning disorder.

Analysis from Case Study

Chris, a child diagnosed with NLD, was able to read before she started school. On a widely used intelligence test, she achieved a verbal IQ score of 120 and a performance IQ score of 102 indicating that she has high functioning verbal ability that is not matched by her nonverbal ability. When she was in preschool she had difficulties in comprehending, transitioning, socializing with other peers, and making self-decisions. She was unable to choose how she wanted to play during free-choice time because reading was the only activity Chris enjoyed in school. When someone stopped her from reading, she became belligerent and refused to comply. This behavior caused the other students to become wary of being close to Chris during free-choice time. When Chris became a 1st grader, she was exceptional in reading and spelling. She was a fast learner with high auditory attention ability. She also liked to create imaginative stories. However, she was not interested in writing down her stories because handwriting was a challenge. Moreover, Chris struggled with math and tended to avoid the

teacher's attention during math class. Aside from math, her scores on other achievement tests were higher than average.

Chris also showed some difficulties in music and art classes. The music class included lots of rhythmical activities. Chris mostly excused herself from those activities to use the bathroom or read books. Drawing, coloring, and creating were the main activities in the art classes. Chris rushed to finish these activities in order to read books. When her art creation was returned to her with feedback to revise, she got angry and threw away her art. Due to her lack of physical coordination and endurance, gym classes were also not enjoyable for Chris. She refused to go to the playground for activities.

This case study contains multiple prognostic factors for NLD. NLD impacted the child's academic and social activities. Chris had difficulties with handwriting, math reasoning, and fine motor skills. These difficulties are related through deficits in visual processing, motor function, and the child's social/emotional profile. Children with NLD generally show lack of both gross and fine motor skills. In this case study, the gym classes preponderantly required gross motor skills (e.g., big movements) and involvement of larger muscles. The handwriting and art projects required mostly fine motor skills (e.g., dexterity) and use of small muscles. Regardless of size of movements, children with NLD demonstrate inadequate kinesthetic processing due to weakness of spatial perception. Moreover, non-reaction towards non-verbal signs is significant evidence of NLD. The case study also contains a significant cue to Chris's diagnosis with NLD by emphasizing how well she responded to auditory directions.

The natural history of NLD shows that symptoms of NLD may be confused with those of ADHD and what used to be termed Asperger's syndrome (a part of ASD). However, main indicators of NLD include critical deficits in visual-spatial processing, nonverbal recognition, and kinesthetic discrepancy. Challenges in these areas greatly impact how children with NLD improve in academic and social/behavioral performances (Palombo 2006).

Clinical Expression and Pathophysiology

Nonverbal learning disorder is a disability characterized by accurate psycholinguistic skills and impoverished visual-spatial orientation, tactile-perceptual, psychomotor, and non-verbal problem-solving skills. These strengths and weaknesses are observed in the following ways:

Assets	Deficits
Intact repetitive motor skills	Bilateral tactile-perceptual and psychomotor deficits (primarily left side)
Responsive to learning through repetition and the auditory modality	Impaired visual discrimination
Well-developed auditory perceptual skills	Impaired visual-spatial organization (e.g., drawing patterns from memory)
Well-developed rote verbal and verbal memory skills	Difficulty with novel and complex situations
Ability to sustain attention to simple, repetitive verbal information	Deficits in nonverbal problem-solving concept formation, hypothesis testing, and use of feedback
Strong receptive language skills including rote verbal memory and verbal associations	Difficulty with cause-effect and recognizing incongruities
Advanced phonemic awareness, including blending and segmentation	Verbose with poor pragmatics (i.e., miss social cues), including inefficient prosody and over reliance on language for relating socially and decreasing anxiety
Average single-word reading and spelling skills	Deficits in math (i.e., functions, decimals, percents, ratios, estimation, geometry, and any visual-spatial math function)
	Impairments in social perception, judgment, and interaction skills, including tendency to withdraw
	Increased risk for suicide

Adapted from Hooper (2000), Rourke and Tsatsanis (1996), Rourke et al. (2002)

In addition to the challenges outlined in the chart above, deficits in higher-level reasoning and problem-solving skills impact on social-emotional learning of an individual with NLD (Rourke 1989). In other words, children with NLD often lack executive functions related to cognitive abilities. These functions engage with complex goal-directed behavior and adaptation in environmental changes. Because these executive functions require self-monitoring and self-awareness to produce appropriate behavior, children with NLD commonly show difficulties with cause-and-effect reasoning, problem solving in various social contexts, and time perception. These are the critical foundations and skills needed for social interactions (Palombo 2006). Issues related to executive function also impact breakdown in social interaction. Children with NLD are less motivated to be social with their peers because of difficulty processing new information and adapting to unfamiliar interpersonal interactions (Volden 2004). Psychopathologies are more evident in children with NLD more than neurotypical children. For example, there is greater risk for depression, withdrawal, and suicide in NLD (Fuerst and Rourke 1995). Awkwardness with other social peers is a distinctive feature of NLD.

Mothers of children with NLD have high levels of maternal stress and high levels of dysfunctional interaction with their children. Indeed, the more severe the disability that children have, the greater the stress and emotional breakdown that the parents have (Antshel and Joseph 2006). The lack of relationship between a mother and a young child with NLD will create a challenge to maintain the relationship in later years. Thompson (1997) described the developmental progression of Nonverbal learning disorder and included additional signs and symptoms presented in early preschool age (3–5 years old). These additional symptoms included strong ability in verbatim memory skills, extreme verbosity, development of early reading skills (e.g., strong letter/number recognitions, spelling skills), and use of literal translations. However, symptoms of impaired gross motor development remained, including balance and

body coordination (e.g., problems riding a bike and spatial confusion).

As they grow into elementary school age (ages 6–10), individuals with NLD will demonstrate deficits in copying text, continue to make literal translations, and continue misjudging and misinterpreting social information. At ages 11–14, individuals with NLD will continue having difficulties in understanding emotional expectations and this will lead to miscommunication with teachers and other social peers at school. Furthermore, difficulties with visual-spatial organizational skills become obstacles to children with NDL and their productivity on tasks. The same behavior deficits involving literal translation, misinterpretation, and misunderstanding cause children with NLD to have difficulties understanding abstract concepts as well as communicating with other social peers. Because of these continued, under-appreciated behavior deficits, children with NLD start to experience some level of depression. Although in high school years (ages 15–18) they appear, at best, to be immature in socializing, they will show improvements in some social domains. Peer tolerance tends to increase so that children with NLD may establish intimate friendships. Relationships between sexes will gradually develop. Eventually, their NLD symptoms will disrupt the ability to become independent adults. Their continuing challenges with literal understanding, lack of ability to solve abstract concepts, and visual-spatial impairments will increase their low self-esteem, depression, withdrawal, and anxiety.

Neuroscience studies have shown that NLD involves abnormalities in the right cerebral hemisphere of the brain which is important for nonverbal processing skills. Rourke and colleagues have spent three decades designing a neuropsychological model to explain the strengths and challenges of individuals with NLD. Their work, *White Matter Model*, was published in 1987. White matter refers to long myelinated fibers in the brain. Their work shifted the focus on the origin of NLD from a primary dysfunction of the right cerebral hemisphere to consideration of an underdevelopment of white matter in the brain (Rourke 1987, 1989, 1995; Rourke et al. 2002). This novel idea

stemmed from observations that cerebral white matter malfunctions in various conditions manifesting impairments in perceptual and cognitive functions similar to NLD, such as agenesis of the corpus callosum, in which the large bundle of white matter connecting two cerebral hemispheres has failed to develop. In addition, children who experienced severe head injuries or who have received repeated radiation treatment on their brains may have damage to white matter and, therefore, may have higher risk to develop the symptoms of NLD.

Evaluation and Differential Diagnosis

The fact that NLD does not produce outstanding symptoms on its own, and has considerable similarities to other disorders, necessitates careful consideration of the evaluation and diagnostic procedures for NLD. The clinical diagnosis of NLD evaluates neuropsychological strength and weakness by implementing Rourke's classification criteria and the preliminary communication profile (Rourke and Tsatsanis 1996). Differential diagnosis should involve a comprehensive neuropsychological evaluation incorporating examination of academic, social-emotional, and cognitive skills. An interdisciplinary team approach should be used to assess functional impairments and disabilities. These professional disciplines may include occupational therapy, speech-language pathology, medicine, psychology, and education. It is critical that various professionals and experts work together to establish concrete understanding of the individual's challenges over time and across multiple developmental domains. From a history of the child, physicians can share profiles of the child's impairments with other professionals to prevent missing possible red flags (e.g., poor psychomotor development, clumsiness, and challenges with early handwriting tasks). It is clearly important that the child be evaluated later in their development such as in middle school or high school. A discrepancy in performance IQ and verbal IQ at any stage of development is a critical piece of evidence.

Based on evidence obtained by multiple professionals, schools can support individuals with

NLD using relevant services (Thompson 1996). Assessment of communication skills must proceed along with examinations in semantic (meaning of words) and pragmatic (functional language use) skills, as these are the areas of common concern for children with NLD. Challenges in literacy or language are often observed in the relative strengths with phonological processing (speech sound processing) and syntax (grammar). Children with NLD may seem to have a rich vocabulary because of favorable scores on receptive/expressive language measures (e.g., *Peabody Picture Vocabulary Test-4th edition (PPVT-4)*, *Expressive One-Word Vocabulary Test-2nd edition (EVT-2)*). However, these test measurements are limited by their examination of the use of socially accepted words, use of multiple words across various contexts, or use of those words that occur with less frequency. The tests do not measure the extent to which individuals with NLD miss meaningful contents in their conversations because they do not fully understand the words they are using. Thus, it is essential to evaluate the higher-level semantic skills of children with NLD including understanding of multiple meanings and figurative language. Standardized measures available to administer tests of these linguistic skills include the *Test of Problem Solving-3rd edition (TOPS-3)*, *The Word Test-3*, and the *Test of Language Competence-2nd edition (TLC-2)*. Professionals should be encouraged to collect valuable information on the appropriate social use of language (e.g., conversational turn taking, maintaining and building on topics, and recognizing and repairing communication breakdowns). Assessments may also be implemented by using *Children's Communication Checklist-2 (CCC-2)*, *Pragmatic Protocol, Assessment of Language Impaired Children's Conversations, Topic Checklist*, and *Narrative Analysis* (i.e., analyzing a child's narrative for story grammar and other components).

Treatment

Because the symptoms of NLD are varied, the most efficient treatment for children with NLD

involves establishing individualized goals and specialized instruction. Educators can then coordinate the interventions to produce the best long-term outcomes. These interventions should include functional practices children with NLD can use on a daily basis. The ultimate goal of all interventions is to improve active processing of new information by helping individuals with NLD to explain concepts, instructions, and stories in their own words rather than relying on repeating known information verbatim from memory (Rourke 1995). Sets of compensations, accommodations, modifications, and individualized learning strategies (CAMs) should be implemented for the appropriate needs of the individuals with NLD (Thompson 1997). For example, a child with NLD may be provided with extra time to navigate himself to a place when given verbal cues. This intervention will require the child to practice utilizing his understanding of spatial and directional concepts. Task analysis is a procedure based on Applied Behavior Analysis (ABA) that is another intervention strategy for children with NLD. Task analysis is a strategy that divides a targeted behavior into a series of step-by-step instructions (Smith 1999). Rather than teaching the multiple steps of the task all at once, an educator can introduce small sets of tasks so that children with NLD have ample time to adapt and process the new information. Depending on the types of tasks, an instructor starts the instruction sequence beginning with the first step (called Forward Chaining) or the children with NLD can start from the last step of the instruction sequence (called Backward Chaining).

Berg (2000) introduced the use of gestalt imagery as an intervention for children with NLD. Children with NLD often get frustrated when creating a gestalt to support their comprehension levels. Since individuals with NLD show deficits in abstract-concept processing, they are not able to organize the parts of a concept from the whole. Implementation of gestalt instruction will help children with NLD to connect incoming language (both oral and written) to prior knowledge. Therefore, these gestalt interventions facilitate smooth socialization of children with NLD by helping them to interpret what they see, hear, and feel

from the surrounding environments. To utilize the gestalt imagery, one needs to learn how to describe a picture, an image, a simple sentence, and then add interpretation and critical thinking to this imaging process (Bell 1986).

The following is a list of accommodations, modifications, and teaching strategies (CAMS) based on the work of Sue Thompson, M.A., C.E. (Thompson 1996):

1. Expectations for this child should always be applied with flexibility, taking into consideration the fact that she has different needs and abilities than her peer group.
2. Independence should be introduced gradually in controlled, nonthreatening situations. The more completely those around her understand this child and her particular strengths and weaknesses, the better prepared they will be to promote attitudes of personal independence. Never leave this child to her own devices in new activities or situations which lack sufficient structure.
3. School assignments which require merely copying text need to be modified or omitted, owing to the visual-spatial nature of such an exercise. Active verbalization and/or subvocalization are the best memory approaches for this child.
4. Adults need to check often for understanding and present information in plain and clear verbal terms (i.e., “spell out” everything). A “parts-to-whole” verbal teaching approach should be utilized. A child with NLD will need to ask a lot of questions, as this is her primary means of gathering information.
5. All expectations need to be direct and explicit. Do not require this child to “read between the lines” to glean your intentions. Avoid sarcasm, figurative speech, idioms, slang, etc., unless you plan to explain your usage.
6. This student’s schedule needs to be as predictable as possible. He should be prepared in advance for changes in routine, such as assemblies, field trips, vacation days, finals, etc.
7. Placement must be in an environment, which has a well-established routine because this child will not decipher nonverbal cues. She cannot adjust well to constant changes in routine (this child lacks the ability to “wing it” in times of doubt) and has learned to fear all new and/or unknown situations and experiences.
8. This child will benefit from cooperative learning situations (when grouped with “good role models”). Active verbalization is an important element in how this child learns.
9. Tell the child everything and encourage her to give you verbal feedback. The most effective instructional procedures are those that associate verbal labels with concrete situations and experiences.
10. Isolation, deprivation, and punishment are not effective methods to change the behavior of a child who is already trying his best to conform (but misinterpreting all kinds of nonverbal cues). If inappropriate behaviors are causing problems at school, a functional analysis and behavioral intervention plan detailing a course of action needs to be completed.

[Male Turner](#); [Ras/MAPK pathway syndromes](#)

Short Description or Definition

Noonan syndrome (NS) is a multiple malformation genetic disorder characterized by dysmorphic facies including hypertelorism, ptosis, low-set posteriorly rotated ears, short neck, and relative macrocephaly. Associated features include short stature, chest deformity, undescended testes, muscle hypotonia, frequent learning difficulties, and congenital heart disease most commonly valvular pulmonary stenosis. In 2001 (Tartaglia et al. 2001), a germline mutation in the *PTPN11* gene in the Ras/MAPK (mitogen-activated protein kinase) signal transduction pathway was found to be a cause of nearly 50% of the cases of NS. Since then, a number of other genes in the same pathway have been identified but in about 25% the causative gene for NS has yet to be identified.

Before NS was recognized as a distinct syndrome, some females were misdiagnosed as having Turner syndrome, and many males, given the diagnosis of male Turner, are now recognized as having NS. The recognition of this entity as a distinct new syndrome was presented first in 1963 (Noonan and Ehmke 1963) and then published in 1968 (Noonan 1968). Dr. John Opitz (1985) proposed the eponym “Noonan syndrome” because Dr. Jacqueline Noonan was the first to recognize that the syndrome occurred in both males and females, had normal chromosomes, could be inherited, and frequently had valvular pulmonary stenosis.

Categorization

NS is the most common of a number of conditions that involve a gene mutation in the RAS/MAPK pathway. These include cardio-facial-cutaneous syndrome, Costello syndrome, Leopard syndrome, and neurofibromatosis₁ (NF₁).

Epidemiology

The estimated incidence of NS is 1:1000–1:2500 births. It occurs worldwide with a slight

predominance in males. It is transmitted as an autosomal dominant, but sporadic cases are frequent.

Natural History, Prognostic Factors, and Outcomes

Infancy

NS may be suspected in fetal life because of the frequent finding of cystic hygroma identified on routine fetal ultrasound. This abnormality is not unique to NS and is not uniformly present. If either parent has NS, and the causative gene is known, prenatal testing of the fetus can be accomplished. There is an increased incidence in polyhydramnios but most newborns are within normal range for length and weight. In a minority of infants with NS, the newborn period may be complicated by significant distress due to pleural effusions with respiratory compromise. Dysmorphic facies may be subtle but the presence of pulmonary stenosis should suggest the possibility of NS. Most cases of NS are not diagnosed in the newborn.

Failure to thrive with poor feeding and vomiting is severe enough in about one quarter of infants to prompt hospitalization for evaluation, and many require treatment for reflux and undergo tube feedings. In the remainder, there may be slower than average motor development with both sitting up and walking somewhat delayed probably attributed to decrease in muscle tone. Speech is often delayed.

Childhood

Slow growth in early childhood is common with height falling off the growth curve so that by 4–5 years of age, short stature becomes a real concern prompting both a genetic and endocrine evaluation. The majority of children with NS are not recognized until 6–7 years of age. It is important to consider the diagnosis of NS as early as possible so that early intervention can be started. Learning difficulties in school require evaluation of vision and hearing. Both vision problems and hearing loss are relatively common, and early intervention before starting school should be the goal.

Adolescence

The adolescent with NS often feels out of place with peers. Puberty is often delayed so the growth spurt occurring in peers is delayed in NS making the short stature more evident. Although growth hormone deficiency is uncommon in NS, it does occur and an endocrine evaluation is appropriate. Today, there is an increase in the use of growth hormone in NS even without growth hormone deficiency. There is no question that growth hormone treatment will significantly increase growth velocity and also accelerate the usual delay toward puberty. Some feel that growth hormone treatment will increase the estimated adult height but no control study has been carried out to confirm this. For those with very short stature below the third percentile, the addition of 3–4 in. over expected adult height may make daily living activities easier similar to patients with Turner syndrome. The use of growth hormone in all NS patients with more modest short stature is more controversial. Some concerns include the high cost of growth hormone treatment and the message sent that being short is a real handicap and needs treatment. More attention should be given to preparing the NS individual for adulthood. Most patients with NS graduate from high school and many attend college and go on to become teachers, social workers, nurses, and even physicians and lawyers.

Adulthood

The phenotype of NS changes over time (Allanson et al. 1985) and by adulthood many blend into the normal population. The adult with NS has sharper features with a narrow nasal root and a thin bridge. The neck is longer and webbing more prominent and the skin somewhat transparent. It is interesting that more and more adults are being recognized to have NS for the first time after giving birth to an affected child. This is not surprising since there is variation in the overall physical appearance of a NS patient even among affected family members. Both parents should be carefully evaluated when an infant or child is diagnosed with NS. If NS is suspected, this should be confirmed by genetic consultation so parents can be informed of the 50% risk for subsequent offspring.

Outcomes

There is surprising little information on the natural history of NS. Shaw (Shaw et al. 2007) reported a long-term study on 112 NS individuals (age 12–71 years). There were 57 males and 55 females. Mean years of follow-up were 12 years. This study confirmed the need for long-term follow-up of NS patients. The mean age in that study was only 25.3 years and the mean years of follow-up only 12 years. Most patients felt their quality of life was satisfactory or good. A lack of social life and inability to fit in was cited as a problem for some. The only other publication is a report (Noonan 2005a) of 56 patients diagnosed with NS with a range of age 21–59 years. In this report, 12 (23% of 51) reported a diagnosis of depression and were on antidepressant medication. One had a diagnosis of a bipolar disorder and another with oppositional behavior. Two were recovering alcoholics. It was of interest that the majority of the 30 diagnosed in childhood were unmarried (75%), while the 15 diagnosed as adults (85%) were married, and all of those had one to three affected children which had prompted the diagnosis of NS.

Clinical Expression and Pathophysiology

All patients with suspected NS should have a cardiology consultation including an electrocardiogram and echocardiogram. Over 80% of children with NS have some cardiac problem. Valvular pulmonary stenosis is the most common. Fortunately in many, the obstruction is mild and requires only periodic follow-up. Severe pulmonary stenosis may require surgery if the valve is very dysplastic making balloon valvuloplasty unsuccessful. Many with moderate pulmonary stenosis can be treated with cardiac cath. Atrial septal defects are also common and may be isolated or associated with pulmonary stenosis. Nearly every kind of congenital heart disease has been reported. Even with mild lesions, lifelong follow-up is important. Late developments of valvular and vascular disease have been reported. Although hypertrophic cardiomyopathy is present in only 20% of NS patients, there are particular

mutations, such as RAF1, with a very high incidence. For the uncommon infant with NS and symptomatic HCM, close follow-up is essential. The development of heart failure in such an infant should prompt early referral for heart transplant evaluation since the mortality is high. For the remainder, regular follow-up is needed, but in many the cardiac status remains stable and asymptomatic for many years.

Many with NS experience easy bruising which may be attributed to a number of coagulation factor deficiencies such as factor XI, XII, and VIII and less commonly factor IX and II. Thrombocytopenia and platelet dysfunction are common. In most, the symptoms are mild but in cases of excessive bruising, epistaxis, menorrhagia, or an anticipated surgical procedure, a hematology consult should be obtained. Aspirin should be avoided. Some infants with NS have enlargement of the liver and spleen which may be due to a myeloproliferative disorder which resembles the highly fatal juvenile myelomonocytic leukemia (e.g., Kratz et al. 2005). Fortunately in NS with a PTPN11 mutation, this condition has a favorable prognosis with gradual improvement without specific therapy in the majority of such infants.

Lymphatic problems occur in about 20% and include an increased risk of chylous thorax following cardiac surgery but this condition may occur spontaneously and may be difficult to manage. Both pulmonary lymphangiectasia and intestinal lymphangiectasia are rare findings but peripheral edema often seen in infancy which resolves spontaneously may become a problem in adults. Orthopedic problems such as scoliosis and kyphosis require close follow-up and referral as needed.

Neurologic, cognitive, and behavioral aspects of NS are extremely variable and are still poorly understood. Seizures are not common but occur and are usually responsive to common drug therapy. Arnold-Chiari malformation is uncommon but is increasingly being recognized. Although most individuals with NS have normal intelligence as a group, IQ tends to be ten points lower than unaffected family member or that of the general population (Van der Burgt et al. 1999).

There is a difference depending on the gene mutation. SOS1 mutations as a group have normal intelligence and good school performance compared to PTPN11 (Tartaglia et al. 2007) mutations, although specific PTPN11 mutations have no cognitive delay (Cesarini et al. 2009). Muscle weakness results in some clumsiness, and vision may contribute to poor coordination. As a group, they are happy, animated, social, and active children.

Only recently have there been any cognitive, neuropsychological, and behavior studies of NS related to genotype. Pierpont in 2009 (Pierpont et al. 2009) demonstrated that cognitive impairments were common among individuals with a PTPN11 mutation, while all SOS1 individuals had verbal and nonverbal cognitive skills in the normal range. As expected hearing loss, motor dexterity, and parental education levels accounted for significant variability in cognitive outcome. In a more recent paper, Pierpont (Pierpont et al. 2010) studied the language phenotype of children and adolescents with NS. She studied 66 NS patients and found that variation in language skill is closely related to cognitive, perceptual, and motor factors. There was no evidence that specific aspects of language are selectively affected by NS. Venhaeven et al. (2007) reported in 2008 a study of ten NS patients ranging in age from 16 to 59 years. This study confirmed previous studies showing variability in IQ scores but as a whole in the low-average range. In regard to psychoneuroticism, anxiety, and depression, using a study on a self-report instrument (SCL-90-R) showed higher-than-average results of comorbidity in this population. Conversely, testing on quality of life and satisfaction showed average-to-high satisfaction with different aspects of life. Investigators found the participants as "remarkably friendly, cooperative, and very willing to please." They found no behavioral phenotype associated with NS but measurements of social cognition and adaptation appeared to be somewhat impaired suggesting some degree of alexithymia is present. This term refers to impaired ability to identify and communicate one's emotional state. This finding may help explain the report of depression in adult NS patients.

Noonan Syndrome and Autism Spectrum Disorders

It is somewhat surprising that, although NS involves a germline mutation in a pathway playing a major role in brain development, reports of autism in NS are very few. The two cases reported in the literature include a 3-year-old (Ghaziuddin et al. 1994) with a clinical diagnosis of NS but with little details of his appearance provided to confirm a diagnosis of NS although the clinical description of autism is convincing. The second report is of a 13-year-old with a clinical diagnosis of NS (Watanabe et al. 2011) but the physical description given is limited, and no genetic studies were carried out. The description of autism is, however, convincing. A familial case (Tidyman and Rauen 2008) of Leopard syndrome with high-functioning autism spectrum disorder has also been reported, in which a father and three sons with Leopard syndrome all had clinical symptoms consistent with an autism spectrum disorder. Considering the large number of patients with NS from the available published reports, NS would seem to have fewer reports of autism than the general population.

Evaluation and Differential Diagnosis

NS is the most common of a number of conditions due to a gene mutation in the RAS/MAPK pathway (Romano et al. 2010). These include cardio-facial-cutaneous (CFC) syndrome, Costello syndrome (CS), Leopard syndrome (LS), and neurofibromatosis₁ (NF₁). Cardio-facial-cutaneous (CFC) syndrome, Costello syndrome (CS), and Leopard syndrome (LS) are very rare and may be distinguished by genetic testing. About 10% of patients with NF₁ have a Noonan-like phenotype but most of these will demonstrate a neurofibromin deletion. There is considerable similarity in phenotype and associated problems among all these conditions. Gene testing is available. BRAF, MEK1, and MEK2 are the genes in CFC, HRAS in CS, PTPN11 and RAF1 in Leopard syndrome, and neurofibromin in NF1. Other syndromes to be considered include Aarskog syndrome, which is caused by an X-linked recessive

disorder from a mutation in FGD1 gene; fetal alcohol syndrome, which is caused by maternal alcohol consumption; mosaic trisomy 22, which is characterized by similar facial features but with a chromosomal abnormality; and Turner syndrome, which is characterized by loss of one sex chromosome.

Treatment

Treatment for NS has been discussed under the various systems affected. Early recognition is essential as appropriate management can be started early. Early genetic evaluation should be sought. Genetic testing can be diagnostic but about 25% of NS patients still have no specific genetic test available. There is a need for additional studies in neuropsychological and behavioral aspects of NS so that the most helpful interventions can be started early. A recent publication (Romano et al. 2010) for the primary care physician on management guidelines in NS has recently been published. NS and the other RAS-MPK disorders have stimulated basic scientists to seek more knowledge of this pathway not only for its role in fetal development and cancer but the role of these mutated genes as we age. There is hope that some of the adverse associations such as postnatal short stature, learning difficulties, and progressive hypertrophic cardiomyopathy may be improved with appropriate genetic therapy. There is still much to learn about Noonan syndrome.

Noradrenaline

► Norepinephrine

Noradrenergic System

Yoshihiro Takeuchi

Division of Developmental and Behavioral Pediatrics, Department of Pediatrics, Shiga University of Medical Science, Otsu, Shiga, Japan

Introduction

Autism spectrum disorders (ASDs) are complex neurodevelopmental disorders with a wide range of behavioral manifestations (Persico and Bourgeron 2006). Research in the neurobiology of ASD will lead to optimal treatments for this heterogeneous group of ASDs, and the impact of ASD can be minimized through intensive intervention, especially during early childhood (Holden and Liu 2005; Johnston and Blue 2006; Lam et al. 2006; Persico and Bourgeron 2006).

Abnormalities in brain structure and function are common in ASD patients, but there is variability among subjects. Several reports have described postnatal macrocephaly in ASD patients (Amaral et al. 2008). Qualitative magnetic resonance imaging (MRI) scans suggest the

occurrence of neuronal migration defects in some cases of ASD, and enlarged occipital and parietal lobes have also been reported. Causes of macrocephaly in ASD patients may include increased neurogenesis, decreased neuronal cell death, and increased production of non-neuronal tissue. Because neurotransmitters and neuromodulators are involved in both the differentiation and the maintenance of neurons, their over- or underproduction or availability may influence the numbers of specific neurons in different regions of the brain (Holden and Liu 2005).

Neurochemical investigations in ASD have examined a wide array of transmitter systems, including serotonin, noradrenaline, dopamine, acetylcholine, oxytocin, glutamate, and gamma-aminobutyric acid (GABA) systems. These studies have been complicated by the fact that ASD is a very heterogeneous disorder, which often presents with comorbid behavioral problems (Johnston and Blue 2006; Lam et al. 2006; Koves and Heinzlmann 2007).

Noradrenaline (NA, also known as norepinephrine), an important classical neurotransmitter derived from dopamine, appears first in the notochord and then in neural crest before the differentiation of neuroblasts (Koves and Heinzlmann 2007). Increasingly complex theories have described the functional role of the noradrenergic system, beginning with vigilance, sensory perception, attention, and memory processes, and culminating in complex models concerning prediction errors, decision making, and unexpected uncertainty.

Neuroanatomy of Noradrenergic System

Initial evidence for the existence of monoamine containing neurons in the central nervous system came from pioneering studies of Dahlstrom and Fuxe (1964). The first description of the cortical distribution of noradrenergic terminals was provided soon after by the same group, followed by a wave of neuroanatomical studies using various methods, and culminating in a definitive autoradiographic study describing the extensive projections from a small pontine nucleus to most regions of the brain.

Neurons that synthesize NA are restricted to the pontine and medullary tegmental regions. Seven noradrenergic cell groups, designated A1-A7, have been described in rodents, and most of these have been observed in primates, including human. Groups A1 and A2 are located in the lower portion of the medulla oblongata. Cells corresponding to group A3 lie just dorsal to the inferior olivary complex and have not been observed in primates. Group A4 consists of a band of subependymal neurons extending along the superior cerebellar peduncle. Group A5 is situated in the caudolateral part of the pontine tegmentum and consists of rather loosely arranged cells. Group A6 is a densely packed accumulation of cells within the locus coeruleus (LC), located in the floor of the fourth ventricle at rostral pontine levels, as described in detail below. The cells of the A7 group are situated in the rostral pontine part of the lateral reticular formation and lie mainly medial to the lateral lemniscus (Dahlstrom and Fuxe 1964; Nieuwenhuys 1985; Koves and Heinzlmann 2007).

There are two major and one minor central noradrenergic pathways. One major pathway arises in the LC as the A4 and A6 regions consisting entirely of noradrenergic neurons. The second noradrenergic pathway arises from neurons diffusely distributed in the brainstem of the subcoeruleus region. A third, periventricular system arises in the dorsal raphe nucleus and projects to the pretectal area, habenula, thalamus, and hypothalamus (Nieuwenhuys 1985).

The LC complex, containing approximately half of the total number of NA-synthesizing neurons, is quantitatively the most important noradrenergic center of the brain. The LC is a small-pigmented nucleus nestled in the rostral dorsolateral pontine tegmentum and, in humans, consists of approximately 40,000 neurons with the most widespread efferent projections of any neurons in the brain. Noteworthy is that NA is crucial for the normal development of Cajal-Retzius cells, which are responsible for the migration of other neurons and the formation of lamination in the cortex (Koves and Heinzlmann 2007). All layers of the cortex are innervated with a regional specificity in the density and distribution of noradrenergic

varicosities. Some areas of the cortex are more highly innervated (Chandler 2016). This innervation has been found to be higher in the frontal cortex, compared to the motor somatosensory and piriform cortices, with the highest found in the anterior cingulate cortex (Agster et al. 2013). Although the prefrontal regions receive the most NA innervation, the insular cortex uniquely is innervated by both the LC and non-LC derived NA containing fibers.

NA functions as a neurotransmitter and/or neuromodulator that can be distributed via the bloodstream, via volume transmission as well as having widespread release sites such as synaptic varicosities. Massive axonal arborizations have huge numbers of release sites (Agnati et al. 2010; Dayan 2012). Neuromodulation can aid in hyperpolarizing or depolarizing neurons, changing their responsivity to input, altering the strengths of synapses, and shaping the plasticity of those synapses. Input from a small number of neuromodulatory cells can abruptly interrupt the activity of neural networks and reorganize the elements into new functional networks (London 2018).

Neurochemical Alterations of NA

NA is a catecholamine that is synthesized from dopamine through the action of the enzyme dopamine beta-hydroxylase. Almost all regions of the brain receive input from noradrenergic neurons, and the cell bodies of the most important system are located in the LC, as described above. The activity of the noradrenergic system is thought to play a critical role in attention, filtering of irrelevant stimuli, stress response, anxiety, and memory. Since many of these functions are impaired in individuals with ASD, researchers have investigated whether noradrenergic functioning is altered. Noradrenergic activity has been assessed in ASD patients by measurement of NA and its central and/or peripheral metabolites in blood, urine, and cerebrospinal fluid (Lam et al. 2006).

Noradrenergic function can be measured in the blood as NA itself, and as its principal central metabolite, 3-methoxy-4-hydroxyphenylglycol.

Unlike some of the other neurotransmitter systems, central and peripheral noradrenergic systems are reported to couple with blood and cerebrospinal fluid concentrations. Some studies examining NA levels in the blood showed higher concentrations in patients with ASD compared to control subjects, whereas the results of other studies failed to show any differences between patients with ASD and normal controls. In addition, the results of studies examining the excretion of NA and its metabolites in patients with ASD have been inconsistent (Lam et al. 2006).

Studies measuring levels of 3-methoxy-4-hydroxyphenylglycol in cerebrospinal fluid showed no significant difference between ASD patients and control subjects. The only consistent abnormal finding with regard to noradrenergic functioning in ASD patients is elevated plasma NA levels, as mentioned above. It is known that plasma NA has an extremely short half-life and largely reflects the state of sympathetic arousal at the time of blood drawing. It is plausible that baseline noradrenergic functioning is normal in subjects with ASD, but that the clinical procedures may lead to hyperarousal and a heightened sympathetic response, resulting in transient high levels of NA in the blood.

Evidence for the relationship of dopamine and NA with ASD was gathered from the studies reported decrease in dopamine- β -hydroxylase activity and increased serum NA levels in children with ASD and in their parents. Study using positron emission tomography (PET) in ASD patients has revealed that increased activity of dopamine transporter (DAT) at the orbitofrontal cortex (Nakamura et al. 2010). A de novo mutation of DAT gene (SLC6A3) in individuals with ASD has been reported (Neale et al. 2012).

NA-Related Genes and the Expression of ASD

Genes Involved in the Synthesis of NA

NA is synthesized from dopamine by dopamine-beta-hydroxylase. Therefore, it is of interest that mothers of children with ASD had a higher frequency of alleles associated with lower

dopamine-hydroxylase activity, suggesting that maternal genes may influence early development of the fetal brain. Tyrosine is synthesized from phenylalanine by phenylalanine hydroxylase, and defects in the gene for phenylalanine-hydroxylase result in phenylketonuria, which is often associated with ASD. Tyrosine hydroxylase is the rate-limiting enzyme in the synthesis of dopamine and NA. The tyrosine hydroxylase gene is located on the short arm of chromosome 11 at 11p15 and has been examined as a candidate gene in a number of different populations, including schizophrenia (Holden and Liu 2005).

Genes Involved in the Catabolism of NA

Monoamine oxidase A (MAO-A) catalyzes the oxidation of three neurotransmitters (dopamine, NA, and serotonin) implicated in the pathogenesis of neurobehavioral disorders. The MAOA gene is located on the X-chromosome at p11.23–0.4. Mutations or variations that affect levels of this enzyme may result in changes in the levels of NA. Both aggression and borderline retardation have been reported in a family with a point mutation in the MAOA gene. In addition, MAOA deficient mice show both enhanced fear conditioning and passive avoidance learning. A frequent occurrence of aggressive behaviors and apparent lack of emotional responses in some individuals with ASD have been reported. Thus, this gene is considered a candidate gene for either an etiological role in ASD or in modifying the phenotype in affected individuals (Holden and Liu 2005). A variable number tandem repeat polymorphism in the promoter region of the MAOA gene has been reported to be associated with several psychiatric disorders. The two most common polymorphisms are the 3- and 4-repeat alleles, which are thought to be associated with decreased and increased transcriptional activity, respectively (Roohi et al. 2009).

Genes Involved in the Uptake of NA

Genes affecting the synthesis and breakdown of NA and NA transporters, as well as receptors, can affect the effective level of dopamine and NA available at the synapse. Therefore, these genes should be considered as candidate genes for ASD.

The NA transporter is expressed in the placenta and is exposed to maternal blood, suggesting a role for this protein in the transplacental transport of the neurotransmitter to the fetus. Altered transport, either increased or decreased, is likely to affect exposure of the fetus to inappropriate neurotransmitter levels, resulting in abnormal brain development. The NA transporter gene is located on chromosome 16 (16q12.2). Using linked polymorphisms, these transporter genes appear to be important in susceptibility to ASD (Holden and Liu 2005). A de novo mutation of DAT gene in individuals with ASD has been reported (Neale et al. 2012). The NA transporter gene (SLC6A2) was found not to be associated with cognitive and behavioral phenotypes of patients with ASD (Park et al. 2014). Direct postmortem study of ASD found no difference in the total cell count, the volume of the LC, and the numerical density.

The New Theory

The theory proposed by Mehler and Purpura (2009) is that ASD is caused by impaired regulation of the LC. The theory stems from decades of anecdotal observations that some children with ASD exhibit improved behaviors and enhanced communication during febrile episodes. The behavioral-state changes associated with fever in ASD are considered to depend upon normalization of a functionally impaired the LC-noradrenergic system. Fever transiently restores the modulatory functions of the LC-noradrenergic system and ameliorates autistic behaviors (Mehler and Purpura 2009). There is also evidence for separate corticotropin-releasing hormone inputs to the LC that specifically modulate noradrenergic neuronal activation by physiological and environmental stressors (Mehler and Purpura 2009). Prenatal stressors, appropriately timed and sufficiently intense, could also be important in dysregulating the LC-noradrenergic system. LC neurons may be selectively vulnerable to stress-induced functional dysregulation. Prenatal stressful events are reported more frequently in mothers of children with ASD than in mothers of normal control children. A significant increase in ASD

prevalence following maternal exposure to hurricanes and tropical storms has been reported. Furthermore, maternal exposure to severe storms at mid-gestation results in the highest prevalence of ASD in affected cohorts. LC activation is considered to occur when there is a change in environmental imperative, such as the appearance of a novel, unexpected event, or a change in stimulus-reinforcement contingencies. In trials, LC neurons are driven by stimuli that require a rapid behavioral adjustment such as a preparatory signal or an unexpected reward. The LC-noradrenergic system is dysregulated by the interplay of environment, genetic, and epigenetic factors, such as chemical substances both within, as well as outside the genome, that regulate the expression of genes. It is believed that stress plays a central role in the dysregulation of the LC-noradrenergic system, especially in the latter stages of prenatal development when the fetal brain is particularly vulnerable.

The new hypothesis has been proposed by London (2018) to reframe the conceptualization of ASD. Much of the pathology observed in ASD is due to inadequate regulation of circuits rather than intrinsic flaws in the circuitry themselves and the activating and deactivating of circuitry is a central function of the noradrenergic system that plays a central role and explains much of the dysregulation which create the symptoms present in ASD, although other neuromodulators play an important role. Flaws in the functioning of the noradrenergic system are likely not due to primary pathology in the LC neurons themselves, but rather might be secondary to afferent input to the LC or a deficit in the circuitry. This hypothesis needs to be understood as dysregulation rather than hyper- or hypo-functioning. Thus, ASD could be conceptualized as a disorder largely due to a failure of homeostatic mechanisms.

Clinical Implications

Benefits from NA agonists and antagonists in ASD patients have been reported, inconsistent, and clouded with adverse events. Tricyclic antidepressants such as imipramine, desipramine, and nortriptyline are NA reuptake blockers, although they

have other actions, such as dopamine presynaptic reuptake blockade. Both desipramine and clomipramine reduced hyperactivity, whereas clomipramine had additional effects on stereotypic, compulsive, and ritualistic behavior (Lam et al. 2006). Alpha 2 agonists such as clonidine and guanfacine, which dampen NA action, may be helpful for managing hyperactivity, impulsivity, and irritability in young people with ASD. These findings suggest a role of the noradrenergic system in ASD or some of the behaviors that are often present in persons with ASD (Holden and Liu 2005). Postsynaptic beta-adrenergic blockers such as propranolol and nadolol may be useful for managing aggression, self-injury, and agitation (Ward et al. 2013), but they appear to have no consistent effect on manifestations of ASD (Lam et al. 2006). The use of molecular biology to validate clinical psychiatric phenotypes in children with ASD may clarify the response to treatment and long-term clinical management (Roohi et al. 2009).

The neuromodulation of the brain of individuals with ASD could be a powerful strategy, as virtually all of the medications used in psychiatry function as neuromodulators operating on the serotonin, dopamine acetylcholine and GABA, as well as NA neuron systems. Through recognition of the neuromodulatory mechanisms for the symptoms, treatments can be devised (London 2018).

Norepinephrine

George M. Anderson

Laboratory of Developmental Neurochemistry,
Yale Child Study Center, Yale University, New
Haven, CT, USA

Synonyms

Noradrenaline

Definition

Norepinephrine (NE) is a central and peripheral neurotransmitter. The cell bodies of most NE neurons in the brain are located in the brain stem, but project throughout the central nervous system where they are especially important in arousal and attention. NE is also the principal neurotransmitter of the sympathetic nervous system in the periphery (the body), a system critical in arousal and which is closely integrated with the central NE system. Norepinephrine is produced from the essential amino acid tyrosine after ring and side-chain hydroxylation and decarboxylation. Measurement of NE and a range of related compounds in cerebrospinal fluid, plasma, and urine have indicated that global basal function of central and peripheral NE appears unaltered in autism; however, the NE systems may be hyperresponsive to stress.

Synonyms

[Bell-shaped curve](#); [Normal distribution](#); [Standard normal distribution](#)

Definition

The normal curve represents the shape of an important class of statistical probabilities (see Fig. 1 below). The normal curve is used to characterize complex constructs containing continuous random variables. Many phenomena observed in nature have been found to follow a normal distribution. Some human attributes such as height, weight, intelligence, and even social skills can be said to be normally distributed. For example, most people's height clusters around the population mean, and an equally small proportion of people are represented at either extreme end of

the distribution. When represented graphically, the resulting shape resembles that of a bell where there is a single peak at the mean, while the tails extend to the right and left into infinity. Thus, the probability of being 5'10" is relatively high, while the probability of being 7'4" is much smaller. Raw data from any number of disciplines can be transformed into *standard scores* using a simple formula. Once scores have been standardized, the mean of the curve = 0 and the standard deviation = 1. This is referred to as the *standard normal distribution*. Performance on most major standardized tests of intelligence produces standardized scores defined as IQ score and reflects a population mean of 100 and a standard deviation of 15 points. The normal curve is the most prominent probability distribution model used in statistics and psychometrics.

All normal distributions comply with the following postulates:

- 68% of all scores fall within + or – 1 SD from the M.
- 95% of all scores fall within + or – 2 SD from the M.
- 99% of all scores fall within + or – 3 SD from the M.

Normal Language Development

Megan Lyons
Laboratory of Developmental Communication
Disorders, Yale Social and Affective
Neurodevelopment of Autism Program, Yale
Child Study Center, New Haven, CT, USA

Synonyms

[Child language](#); [Language acquisition](#)

Definition

Normal language development involves the acquisition of the rules for producing and understanding the sounds, words, sentences, and conventions for their socially appropriate use in the speech community in which a child is living. Language acquisition is a uniquely human capacity. Although there are many forms of animal communication, these do not show the grammatical generativity or cultural transmission characteristic of human languages (Tomasello

2008). Milestones of communication acquisition, such as first words by 12 months, word combinations by 24 months, and sentences by 36 months, are often used to monitor language growth in children and help parents and professionals determine whether a child is showing signs of falling behind and needing intervention. “Communicative competence,” the ability to use language in an age-appropriate way to accomplish social goals, depends on the acquisition of skills in each of three domains of language specified by Bloom and Lahey (1978): form, content, and use. Form refers to the acquisition of rules for producing sounds to form words (phonology) and words to form sentences (grammar); content refers to vocabulary development and understanding the relationships between words (semantics); use refers to pragmatic aspects of language that govern its social appropriateness. Early communication warning signs for infants or toddlers who may be at risk for developmental disorders such as hearing impairment, autism, language, or developmental delay include failure to respond to sound or voice by 4–6 months; failure to babble or respond to name by 12 months; lack of awareness of and interest in others by 12 months; failure to talk, attempt to communicate, or show interest in pretending by 18 months; producing very few words by 24 months; and failing to combine words by 30 months. In addition, any child who loses previously developed speech-language or social skills may be evidencing risk. Children presenting with these signs should receive evaluations for developmental disabilities with experienced early interventionists. It is very common for children with ASD to show delays in language development; however, many children (10–15% of toddlers) show delays in language acquisition that are NOT associated with ASD. In these children, 75% resolve their language delays by the age of 5 and go on to have adequate language and school achievement.

[Developmentally appropriate practice](#)

Definition

A principle that promotes providing services for individuals with developmental disorders (e.g., autism spectrum disorders, or ASDs) and learning disorders in order to ensure their access to environments and experiences as similar as possible to those available to typically developing individuals. Nirje (1980) defined normalization as making “the regular circumstances and ways of life or society” (p. 33) available to individuals with learning difficulties.

When first adopted, normalization was instrumental in reducing the frequently inhumane institutionalization of these individuals and providing both community-based and other alternative services. The normalization movement began in the 1960s and 1970s in Scandinavia, with other European countries and the United States following. Initially, normalization served as a philosophical foundation for reorganizing the provision of services for individuals with developmental delays (Rehm and Bradley 2005). Following the normalization-inspired

deinstitutionalization movement, some interventionists and researchers have contended that normalization is not the ideal approach to current interventions for ASDs and have argued instead for the necessity of a more individual-focused and strength-based philosophy (e.g., Mesibov 1990). However, normalization has continued to be an overarching philosophy in approaches to treatment for ASDs and other developmental disabilities.

Normalization reflects the need for individuals with ASDs and other disabilities to have access to equality, quality of life, and human rights (Renzaglia et al. 2003). This concept serves as an ideological framework for inclusion, a principle emphasizing the need for programs to support integration of individuals in schools, neighborhoods, and communities, regardless of disability status. The Americans with Disabilities Act and similar laws in other countries, which prohibit discrimination against individuals based on disability, are also consistent with normalization.

In theory, normalization is designed to be applied along a continuum of disability, with various levels of inclusion possible, depending on the level of impairment. Because of the difficulty of conducting randomized controlled studies of normalization practice, current evidence on the outcomes of inclusion practices in schools is preliminary (Ferraioli and Harris 2011). Inclusion of children with ASDs who have not received early intensive behavioral intervention or who have not made significant treatment gains is not supported, but inclusion for children who have made these gains can more often be feasible and successful (Ferraioli and Harris 2011).

Definition

Normative data is data from a reference population that establishes a baseline distribution for a score or measurement, and against which the score or measurement can be compared. Normative data is typically obtained from a large, randomly selected representative sample from the wider population. They can be used to easily transform individual scores or measurements directly into standardized z-scores, T scores, or quantiles. Examples of psychological tests that make use of normative data in scoring include the Wechsler Adult Intelligence Scale (WAIS), the Wechsler Intelligence Scale for Children (WISC), and the Vineland Adaptive Behavior Scales. Normative data can also incorporate additional variables such as age and gender, when these variables are expected to have significant effects on the distribution of measurements; head-circumference-for-age, height-for-age, and

Norm-Referenced Assessment

- [Language Tests](#)

Norm-Referenced Testing

Michael Berger

Department of Psychology, Royal Holloway, University of London, Egham, Surrey, UK

Norm-referenced testing measures by comparing a characteristic of an individual with the same

characteristic in comparable group of others, the normative group.

Assessment or evaluation of individuals with ASD commonly involves psychological or psychometric tests. These are systematic (rule-governed or standardized) procedures devised to measure psychological characteristics. Commonly, these attributes, characteristics, states, and functioning are not directly observable but are inferred from behavior – what people say and do. Psychological tests are designed to provoke specific instances of behaviors believed to reflect the attribute of interest, enabling these to be quantified: getting someone to complete shape puzzles and then counting the number correctly completed is a way of quantifying behaviors assumed to reflect underlying spatial abilities; or the count of the number of “Yes” answers to questions about the presence or absence of certain characteristics might be used as the basis of an index of the severity of ASD characteristics.

The number of correctly completed puzzles or other index derived directly from performance constitutes the “raw score” which, on its own, is meaningless. Meaning is achieved when the raw score is compared with some standard or norm, such as the average performance of comparable individuals – a normative group – on the same tasks. The number of correct responses or answers can be compared with the group average: if above the group average, it is then inferred that their *ability* is above (the group) average. Likewise, a scale to identify severity of ASD symptoms may contain a list of clinical signs and a severity rating scale for each. The total of the severity ratings when compared with the average score of a group of individuals diagnosed with ASD provides a measure of severity. Generally, where an individual’s raw score on a test can be interpreted in relation to an index from a group given the same test, the procedure is a “norm-referenced” test. There are a number of different but interchangeable ways of expressing this comparative relationship using more refined units, including percentiles, standard scores, T-scores, and stanines (Kaplan and Saccuzzo 2009).

The nature of the normative data is a key determinant of the interpretability of any test. If the psychological attribute is something common to people, for instance, intelligence, the normative criterion should be derived from a large sample representative of the population with given the same test. This would enable interpretations such as “X’s” intelligence (a test score from a test designed to measure intelligence) is above, similar to, or below the average. A norm-referenced test for a particular feature of ASD such as degree of social interest among individuals with ASD would require its reference group to be a representative sample of individuals reliably diagnosed with ASD given the same procedure.

Appropriate representative sampling is one of the many requirements for a *clinically acceptable test*. Other requirements include instrument validity (evidence that it measures what it is supposed to) and other indicators of test quality (Groth-Marnat 2009; Kaplan and Saccuzzo 2009). A *clinically acceptable test result* will depend on the use of a valid test with a normative group whose relevant main characteristics (age, gender, etc.) match those of the testee, cooperation of the testee, and a competent tester.

Definition

Nortriptyline is a prescription drug in the group of tricyclic antidepressants initially FDA-approved

for medical use in the year 1964 whose active ingredient nortriptyline hydrochloride has the chemical formula $C_{19}H_{21}N \cdot HCl$. This drug inhibits histamine, 5-hydroxytryptamine, and acetylcholine activity; increases the pressor effect of norepinephrine; and blocks that of phenethylamine. Nortriptyline is metabolized by the liver. This drug is FDA-approved for the treatment of depressive symptoms especially endogenous depression and can be used to treat symptoms of ADHD and Tourette's disorder. Observed side effects include sedation, anticholinergic effects, weight gain, and orthostatic hypotension.

Historical Background

The history of autism in Norway is not very well documented. However, we know that the first diagnosis using the term autism was applied during the 1950s, as a result of Leo Kanner's seminal work in the early 1940s (Kanner 1943). During the 1950s and 1960s, most individuals diagnosed with autism were institutionalized in centralized institutions, so-called institutions for "the mentally retarded" together with other disabled and impaired individuals. The National Competence Program for Autism released a report in 1997, which dealt with the life span and quality of life for ten of the first diagnosed individuals in Norway (Solbakken 1997). At that time, the individuals were in their late 40s, and the parents which were interviewed were in their elderly days. The general commonalities reported for the cases comprised institutionalizing, few resources, lack of individual facilitation, abuse, and malpractice during the 1950s, 1960s, and parts of the 1970s. Normally, the parents of children who were diagnosed with autism in this period were resourceful and had contacts within the field of autism, whereas others were often diagnosed with oligophrenia. Treatment was often related to sedation by drugs and strapping, and there was a lack of structured behavioral and skill training. The institutionalization was more

custody facility than anything else during this period of time.

After Norway had become an increasingly prospering oil nation in the late 1960s and during the 1970s, major changes happened in both the health sector and also in the educational system. There was a heavy debate in the 1970s and 1980s focusing on the wrongdoings of the larger institutions, and the human right to participate in the society was proclaimed. A law regulating special schools for disabled was incorporated into the general law of education in 1975, and the responsibility for education and training of children with autism was transferred from the state-funded institutions to each county council which resulted in a reduction of the larger institutions and a stronger focus on special schools for children with disabilities. Noteworthy, this implied that children and individuals with autism passed the same system as individuals with other disabilities during the time span from the 1950s to as late as the 1980s. In 1965, the Autism Association of Norway (Autismeforeningen) was established; however, it was not before 1982 that the same society established a professional autism advisory board with the intended goal of securing parents, caregivers, teachers, and special education teachers with professional advice on autism. Both parents and professionals were recommended to partnership through the autism association. Today, the association has approximately 4,500 members across Norway.

Together with a number of new educational laws and governmental regulations during the 1990s and early 2000s, the prevailing special schools were discontinued, and children within the autism spectrum and other disabilities were included into their local kindergarten and school. Though extra resources were made available through assessments, the educational school psychology services enable them to participate in special need education programs provided by specially trained teachers. Over the past two decades, the assessment and diagnostic procedures have been conducted by specialized child disability clinics (habilitation units or child and adolescent

psychiatry), which can be found in each county in Norway. Norway has a public healthcare system, securing everyone the right to the same assessment and diagnostic procedures. Children with autism are mostly living at home with their parents, attending regular kindergartens and schools mainstreamed with typically developed children, with follow-up by the local special education advisors. Intervention methods used in Norway during the 1980s, 1990s, and 2000s have been primarily either a combination of visual communication training or TEACCH (Treatment and Education of Autistic and Related Communication Handicapped Children) or ABA (applied behavior analysis) (Lovaas et al. 1981).

Legal Issues, Mandates for Service

Norway has a wide range of services for children with special need and which are governed by law. All children, including those with disabilities such as an autism spectrum disorder, have the right to an equal education that considers each individual's needs. Those with special needs have the right to an individually tailored school day with special education (The Norwegian Education Law 1998). There are different financial aid schemes for individuals with ASD and their families. The Norwegian Work and Welfare Agency (NAV) provides individuals with different impairments of financial aid if their impairment necessitates extra care and supervision. This financial aid shall also ensure stimulation, education, and training at home. The same agency also offers an extra financial aid to those who have additional expenses related to the diagnosis, e.g., if a special diet creates additional costs to the family (The Norwegian Work and Welfare Agency 2014).

Each municipality is responsible for handling applications for subsidies for care from parents or caregivers of children with disabilities such as autism. Such a subsidy can be given as a form of salary that is often given to parents with an additional and heavy workload as parents of a child/children with disabilities (The Norwegian Department of Health and Care 2011). All caregivers of children with disabilities are also entitled to

20 days with full payment to stay at home with sick children.

Diagnosis and Prevalence

With the ICD-10 (1992), which is the diagnostic system used in Norway, the term autism spectrum disorders and the subgroup diagnoses was established in Norway as a way to standardize the diagnostics and assessment of individuals suspected for ASD. There are national guidelines for assessment and diagnostics of children with suspected ASD. The guidelines, however, are not detailed and are subject to different practice at each clinic. A regional study conducted in the southeastern part of Norway indicated that age at diagnosis is during preschool age at approximately 46.4 months and thus resembling similar countries' diagnostic age (Larsen 2015). Another study using the Norwegian Patient Registry indicates that some of the subgroups within ASD often is not diagnosed until late childhood or early adolescence (Surèn et al. 2012).

Sponheim and Skjeldal (1998) reported prevalence estimates in Norway to be approximately 4–5 per 10,000 for childhood autism in a population of children from 3 to 14 years, a somewhat low prevalence compared to other studies at the time, though they focused on autistic disorder specifically and did not recruit children across the whole spectrum. A recent study indicated a fourfold increase with prevalence of 51 per 10,000 when considering the whole range of the spectrum (Isaksen et al. 2012). Other estimates from other studies with Norwegian samples (Posserud et al. 2010; Surèn et al. 2012) indicate that there has been a rise in prevalence of ASD akin to what is typically found in other international studies (e.g., UK and US).

Overview of Current Treatments and Centers

Norway has a public health system, providing all individuals the same rights to assessment and treatment. Each regional hospital and all the

major university hospitals are state funded and provide assessment and some kind of intervention for children with suspected and diagnosed ASD. There are national guidelines for assessment and diagnostics of children with suspected ASD. The guidelines, however, are not detailed and are subject to different practice at each clinic. Current intervention programs provided by the hospital clinics are mainly ABA and derivatives of ABA (such as Early Intensive Behavioral Interventions (EIBI)). Many use versions of Picture Exchange Communication System (PECS), a form of augmentative and alternative communication for children with ASD and limited language. There exist some regions in Norway where pivotal response therapy (PRT) is the most established intervention method; however, this is only the case in a fraction of Norway's 19 counties. The municipalities are also responsible for intervention and training in the context of kindergartens and schools; the most used intervention focus is parts of the TEACCH method, whereas hospital clinics are to a higher degree recommend ABA and PRT also in kindergartens and schools. There are currently agencies in each healthcare region in Norway dealing with among other autism spectrum disorders. Currently, there still exist a few schools that act as resource centers for children with ASD: Nordvoll and Haug in the Oslo region and Frydenlund in Drammen as the most known. They teach a substantial number of pupils, both in the school, but also through supervising other schools working with children with ASD.

Overview of Research

The most significant research in Norway on ASD during the last 10 years is the MoBa study (mother-child study), a longitudinal pregnancy population cohort, following over 100,000 children as they grow older. Linked to this study is the Autism Birth Cohort study (Stoltenberg et al. 2010) with the purpose of identifying all children with ASD in MoBa. The key aims are to disentangle causes of ASD, both genetic and environmental and their interaction, linked to timing of exposure. The most known publication from this study is mother's

usage of folic acid around conception and the reduce risk of having a child with autistic disorder (Surén et al. 2013b). Other Norwegian studies have investigated a range of topics such as Asperger syndrome related to the theory of mind (Kaland et al. 2002, 2008), comorbidity (Gjevik et al. 2015; Bakken et al. 2010; Helverschou et al. 2011), language (Kalandadze et al. 2016; Nordahl-Hansen et al. 2014; Tetzchner and Martinsen 1981; Vulchanova et al. 2012) and ASD related to symptoms of depression (Andersen et al. 2015). Different researchers have also been involved in publications related to screening (Havdahl et al. 2016; Posserud et al. 2009; Stenberg et al. 2014; Øien et al. 2016) and other issues of measures and assessment of persons with ASD (e.g., Bishop et al. 2016; Øien and Eisemann 2016; Nordahl-Hansen et al. 2016). Some of the notable psych-educational treatment studies have mainly targeted preschool children and investigated effects of early intensive behavior interventions (Eikeseth et al. 2002), low-intensity behavioral treatment (Eldevik et al. 2006), and joint attention and joint engagement intervention (Kaale et al. 2014).

(Most studies and researchers on ASD in Norway is conducted or linked to non-private institutions including different universities, university hospitals, and university colleges.)

Social Policy and Current Controversies and Training

The largest organization is the Norwegian Autism Association, which is a parent and care provider organization with approximately 4,500 members with the aim of increasing the knowledge about ASDs among parents, teachers, other professionals, and the individuals with ASDs themselves. Besides this organization, there is a lack of social interest and focus on ASDs in Norway. The latest prevalence study in Norway showed that 0.9% of all children aged 12 were diagnosed with ASDs, and the number for children between 6 and 12 years old was 0.6% (Surén et al. 2013). There are few organized training programs for parents, teachers, and other professionals, with differences between the 19 counties. However,

the regional competence units and hospital clinics offer various courses for parents, teachers, and others who are interested in learning more. Obviously, there is much room for improvement and especially for developing national guidelines for intervention for children and individuals with ASDs in Norway.

Notice of Recommended Educational Placement (NOREP)

Debra Dunn

The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Synonyms

[IEP signature page](#)

Definition

The Notice of Recommended Educational Placement, or NOREP, is a form completed at the end of the process of developing an individualized educational program (IEP) for a student receiving

special education services. It must be provided to parents whenever a school district or other educational entity proposes to change the student's program or placement. The NOREP form summarizes the educational placement for the student and explains the parents' rights to agree or disagree. By signing the NOREP, parents agree to the placement decisions contained within the IEP as well as the IEP goals and specially designed instruction that will govern the child's special education program. If parents disagree with the provisions contained within the IEP and NOREP, the NOREP form provides options for requesting an informal meeting, mediation, or due process hearing. By requesting mediation or a due process hearing, parents of school age children can ensure that their child will stay in his or her current educational placement until dispute resolution occurs. This benefit is called the stay-put requirement or pendency. Parents may agree with portions of the NOREP and IEP and disagree with other parts. In such instances, the parents may indicate the provisions accepted on the NOREP form and note the areas of disagreement.

Nutritional Interventions

Madison Pilato
Neurodevelopmental and Behavioral Pediatrics,
University of Rochester Medical Center,
Rochester, NY, USA

Definition

Nutrition interventions involve supplementing the diet with vitamins, minerals, or other substances in an effort to improve health and alleviate the core symptoms of autism and associated behavior. A common example is for individuals with autism to consume high doses of vitamin B6 combined with magnesium.

Historical Background

Nutritional supplements are often used in an attempt to improve disorders, especially mental

health conditions, and have been used for autism in particular since the 1960s (Levy and Hyman 2008). Bernard Rimland, a proponent of vitamin B6 therapy in particular, traces the origin back to the 1966 report of abnormal metabolites in the urine of children with autism by A. F. Heeley and G. E. Roberts; these metabolites were said to be normalized by vitamin B6 (Rimland 2008). The next article to address the use of vitamins to treat autism was published by Bonisch in 1968, and research continued for the next four decades.

Other nutritional interventions proposed during this time include high doses of vitamins C, A, and D, as well as minerals such as magnesium, iron, selenium, calcium, and zinc. Enzymatic supplements include probiotics and digestive enzymes. Proteins/amino acids, specifically carnosine, tryptophan, and tetrahydrobiopterin, are supplemented because of proposed metabolic disturbances in children with autism (see ► [Amino Acids](#)). Fatty acids (polyunsaturated, omega 3) are administered because they are known to have a role in typical brain development (Levy and Hyman 2008). In addition to dietary supplements and nutrition changes, the following supplements are sometimes used: secretin (see ► [Secretin](#)), melatonin, DMG/TMG (see ► [DMG](#)), piracetam, folate, carnitine, *Ginkgo biloba*, St. John's wort, and inositol (Levy and Hyman 2008; Rossignol 2009).

Rationale or Underlying Theory

Nutritional supplements are given to children with autism because of observed or suspected nutritional, hormonal, metabolic, or digestive abnormalities.

Goals and Objectives

Nutritional supplements are meant to correct nutritional imbalances that some theorize may be responsible for the core symptoms of autism and/or comorbid behavioral disturbances.

Treatment Procedures

Nutritional interventions are supplemented to the diets of children with autism and are administered in pills, capsules, powders, or liquids. A multivitamin/mineral complex may deliver some or all of these vitamins and minerals at once. A common example is combined B6-magnesium treatment.

Efficacy Information

Currently, no reliable evidence exists to support the efficacy of any nutritional supplement for the core symptoms of autism or other behaviors associated with autism. In a 2011 review, Huffman et al. categorized all of the following as weakly supported and in need of more, better research: vitamins, iron, melatonin, fatty acids, and digestive enzymes. Although improvement in social interaction after protein/amino acid supplementation (i.e., carnosine and tetrahydrobiopterin) has been reported, more research is still needed (Huffman et al. 2011). A 2005 Cochrane review of one of the most popular nutrition interventions, combined B6-magnesium treatment, concluded that this treatment cannot be recommended at this time due to methodological weaknesses in the efficacy studies (Nye and Brice 2005). A large majority of the vitamin B6 efficacy studies performed since 1968 (16 of 19) had too many limitations to be included in the review. The remaining three studies found no benefit from B6 therapy but were too small to support definitive conclusions (Nye and Brice). Accordingly, Nye and Brice concluded that at this time, no recommendation can be made regarding this treatment.

Outcome Measurement

Nutrition interventions are intended to reduce autism symptoms and improve adaptive functioning. Therefore, if clinical trials of nutrition interventions are undertaken, outcome measures should include measures of autism symptoms

such as the ADOS and measures of adaptive behavior such as the Vineland. Also, because many nutrition interventions are meant to target other comorbid behavior problems, well-validated measures of these behaviors (i.e., sleep, aggression, self-injury, etc.) should be included.

Qualifications of Treatment Providers

Supplementing diet with nutritional interventions should be discussed with a board-certified physician, as high doses of vitamins, minerals, or other substances may produce side effects.

Object Permanence

Suzanne Macari
Yale Child Study Center, New Haven, CT, USA

Definition

Object permanence is the awareness that objects exist when they are no longer in sight. Between 8 and 10 months of age, infants begin to search for objects that disappear, indicating that they understand that objects still exist after they disappear from view.

Piaget (1952) first described this phenomenon as part of the sensorimotor stage of cognitive development. Over the first several months of life, infants gradually become more and more interested in the environment, particularly in toys and objects. Before about 8 months of age, infants lose interest in objects that are removed from plain sight. During the next several months, however, infants begin to mentally represent objects beyond what is perceived in the moment, and thus begin to search for things that are hidden from view. Object permanence has not been extensively assessed in infants and toddlers with ASD but is thought to be intact in preschoolers with ASD (Carpenter et al. 2002; Dawson and McKissick 1984; Sigman and Ungerer 1981).

Objective

Ruth Eren
Center of Excellence on Autism Spectrum Disorders, Southern Connecticut State University, New Haven, CT, USA

Synonyms

[Behavioral objectives](#); [Benchmarks](#); [Instructional objectives](#); [Milestones](#); [Performance objectives](#); [Steps](#)

Definition

Objectives are often called instructional objectives in the individual educational plan for children

receiving special education services. These instructional objectives are statements that describe the specific instruction for an individual student and provide criteria to measure the effectiveness of the instruction. Mager's performance objective model describes three essential criteria for an objective. An objective must contain a clearly stated behavior or skill, the conditions under which that behavior or skill will occur, and how that behavior or skill will be measured (criteria) to determine achievement of the objective (Mager 1984). It is imperative that objectives be written in terms that are both observable and measurable. An example of an objective that aligns with this model might be: "When given a piece of primary paper and a pencil, Susie will print her first and last name with 100% accuracy in spelling."

Observational Assessments

Louise Spear-Swerling
Southern Connecticut State University, New
Haven, CT, USA

Definition

Observational assessments involve obtaining evaluative information through direct observation.

Although observational assessments could potentially be used in any domain, they most often are used for behavior, social-emotional functioning, and language. A record of the examiner's observations is kept for later interpretation. Considerations in conducting observational assessments include decisions about which specific behaviors to target for observation; when, where, and for how long observations should be conducted; and the validity and reliability of observational data. If observational assessments are reliable, then multiple examiners observing a student's behavior at the same time should have a high degree of agreement in their records of specific behaviors; if observations are valid, they should target behaviors that are well defined and representative of concerns about a student's social-emotional, behavioral, or linguistic functioning.

Interpretation of observational assessments is another important issue. In some situations, as when a teacher has implemented a behavioral or linguistic intervention, post-intervention observational data may simply be interpreted in relation to pre-intervention data on the same student. In other situations, for example, when a child is evaluated for a possible autism spectrum disorder (ASD), observational data may be interpreted with reference to normative data on students of the same age and/or in relation to checklists of behaviors typical of children with ASD.

Observational Learning

Amanda P. Laprime^{1,2} and Ryan Knighton^{1,3}

¹The Center for Children with Special Needs,
Glastonbury, CT, USA

²University of Rochester Medical Center,
Rochester, NY, USA

³Newton Public Schools, Newton, MA, USA

Definition

Observational learning occurs when a person develops a new behavior or skill after watching someone else receive reinforcement for engaging in the behavior or performing the skill. The process of observational learning occurs without any direct instruction or reinforcement (Catania 2007; MacDonald and Ahearn 2015). Observational learning is comprised of four discrete skills: attention, generalized imitation, delayed imitation, and consequence discrimination. In real-life situations, observational learning occurs in the following sequence: (1) observing someone else perform a behavior, (2) observing the consequence for performing the behavior (i.e., reinforcement), and (3) performing the behavior (MacDonald and Ahearn 2015). An example of this would be a young child watching a sibling play with a parent. In an observational learning situation, the sibling would pick up a toy, play with it in a certain way, and the parent would provide praise and interaction. The observing child might then pick up a toy and play in the same way. This would be a naturalistic example of observational learning in that it involves observation of a behavior (toy play), observation of a consequence (parent praise and interaction), and performing the behavior (toy play in the same way). Although observational learning is not a concept or intervention specific to individuals with autism spectrum disorders (ASD), individuals with ASD benefit from the analysis and interventions related to observational learning.

Historical Background

Early work in observational learning focused on the role of the model in behavior change (Bandura and Huston 1961; Bandura et al. 1963). Bandura et al. (1963) demonstrated that behavior change can occur through observation of a model in a natural context without direct reinforcement. Bandura and Huston (1961) also explored the role of vicarious reinforcement in learning new skills after observing a model. They noted that vicarious reinforcement occurs when there is no extrinsic reinforcement for a behavior. Instead, they hypothesized that intrinsic reinforcement may be relevant in this type of learning situation. Additional descriptions of observational learning have included social watching and imitation (Miller and Dollard 1941), modeling, copying, imitation, echoing, parroting, and vicarious behavior change (Greer et al. 2006).

Kazdin (1973) evaluated whether children who observed other children receiving social reinforcement such as praise for target behavior would then engage in the same behavior. Results of the study demonstrated that the participants who observed children engaging in a target behavior then engaged in those same responses without direct teaching or reinforcement. This study further strengthened the conceptual understanding of observational learning (Birnbrauer 1976; Williams et al. 2004). More recent work differentiates observational learning from imitation and modeling. Although imitating is part of observational learning, observational learning also involves responding based on the observed consequences (MacDonald and Ahearn 2015; Taylor et al. 2012).

Rationale or Underlying Theory

A variety of studies have demonstrated the importance of learning from others and found that many individuals with ASD do not learn in this way. For example, individuals with ASD do not always imitate the behavior of others, which is a primary component of observational learning (Williams et al. 2004). We know that individuals with ASD

often require direct, intensive instruction and reinforcement to learn new skills; yet learning in this manner could be time consuming and may require a high level of resources. Learning through observation is not only foundational in child Development, but it is advantageous in maximizing learning opportunities for individuals with ASD who are exposed to a variety of environments. Learning through observation is not only foundational in child development, but it is advantageous in maximizing learning opportunities. Individuals with an ASD are exposed to numerous locations in which they learn and practice new skills. Across these environments, there is a wide variability in terms of direct reinforcement or support for facilitation of expected behaviors. Given this, an understanding of observational learning may facilitate greater inclusion, participation, and learning across a number of environments for individuals with ASD (Greer et al. 2006).

Conceptual analysis of observational learning: The four areas of observational learning are (1) engaging in a behavior already in the repertoire because of on observation of someone else receiving reinforcement for that behavior (i.e., watching someone do something you have done before and doing it because you see them receive reinforcement), (2) learning a new behavior as a product of watching someone else being taught a behavior (i.e., learning to do something new because you saw someone else receive reinforcement for doing something), (3) the acquisition of conditioned reinforcers through observation (i.e., learning to like new things because you saw someone else engaging with an item or activity), and (4) developing the skill of observational learning (Greer et al. 2006). One conceptual analysis which accounts for the emergence of observational learning is that of automatic reinforcement (Gladstone and Cooley 1979; Bruzek and Thompson 2007). Gladstone and Cooley (1979) described that simply doing the same thing you see someone else doing may itself function as a reinforcer for imitative and observational responses. This is important in understanding why children imitate behaviors that are not immediately reinforced. This type of reinforcement is discussed as intrinsic to the child

(Bandura and Huston 1961) and imperative for a robust, independent repertoire of imitation and observation not facilitated by adults.

Goals and Objectives

The goal of observational learning interventions is to teach individuals new skills or behavior through observation.

Treatment Participants

Research on observational learning has evaluated its impact with typically developing children (Greer et al. 2006) and children and young adults with ASD (Taylor et al. 2012; MacDonald and Ahearn 2015). Research has also included individuals who have other types of disabilities such as developmental delay and chromosomal abnormalities (Rehfeldt et al. 2003; Werts et al. 1996), and Down syndrome (Griffen et al. 1992). Observational learning is an intervention that benefits all people. For individuals with an ASD, observational learning is an effective intervention if the individual has the previously described prerequisite skills to learn in this manner.

Treatment Procedures

The procedures of an observational learning intervention vary based on the environment, the model, and the skill being taught. As previously described, observational learning interventions all include the steps of (1) observing someone else perform a behavior, (2) observing the consequence for performing the behavior (i.e., reinforcement), and (3) performing the behavior (MacDonald and Ahearn 2015). Importantly, all procedures require that individuals have mastered a series of prerequisite skills (referenced previously) prior to implementation. If individuals do not have those skills in their repertoire, instruction around each of those skills must precede an observational learning intervention.

Developing the skill/process of observational learning: Research in the field of observational learning has evaluated interventions to teach the skills related to observational learning, as well as assess for an observational learning repertoire (Taylor et al. 2012; MacDonald and Ahearn 2015). Before teaching observational learning, a relevant skill deficit is identified. Next, a scenario involving someone modeling that skill would be created. Scenarios may be embedded into naturally occurring situations, such as during play time, or contrived, such as when a teacher recreates a situation that is often challenging for the individual (e.g., sharing a toy). Peers who perform the desired skill consistently may be used as a model. The individual then observes the model performing the skill and receiving reinforcement for that skill. Lastly, it is evaluated if the individual then engages in that skill independently. Taylor et al. (2012) first assessed if three children with ASD could monitor their peers' reading and subsequently acquire sight words. Pre-assessment showed that observational learning did not occur when children with ASD watched their peers read sight words and receive praise and tokens for reading. Once the children with ASD were taught to watch and repeat what their peers said, a session was then conducted to again test for observational learning. The study showed that directly teaching observational skills increased monitoring responses in all participants with ASD, enhancing the observational learning repertoire. This subsequently resulted in increased accuracy of reading previously unknown words, after observing their peers read and receive reinforcement for reading. In another example, MacDonald and Ahearn (2015) used several tasks to test whether an individual with an ASD demonstrated an observational learning repertoire. One task involved hiding a preferred food under a cup, something less preferred under a second cup, and nothing under a third cup. One person revealed what was under each cup, sampled the food, and commented (e.g., "Yummy!" or "Ew, gross!"). In the case of the empty cup, the comment was, "There is nothing here." The other person observing was then given an opportunity to interact with the three cups. If they chose the cup with a treat,

this suggested that they demonstrated observational learning. Another task involved setting out toys, some working toys and some broken toys. One person interacted with the toys to show the other person which toys worked and which ones were broken. If the next person selected only the working toys, this suggested that they demonstrated observational learning.

Interventions involving observational learning: In addition to teaching direct skills related to observational learning, the literature in this area has demonstrated the efficacy of observational learning as an intervention across a variety of factors.

Firstly, the types of models used during observational learning have varied. Models have included in vivo peer models (e.g., a child may watch another child say, "car" and then receive a toy car), video models (a child may watch a video of another child saying "car" and then receive a toy car), in vivo adult models (a child may watch an adult say "Hi" to another person and receive a hug), and even auditory stimuli (a child may hear on an audio recording an individual make a statement and receive praise for that statement; Werts et al. 1996). Secondly, research in this area has enhanced skill repertoires across a variety of domains. These include but are not limited to play skills (Bruzek and Thompson 2007), academic skills (Ramirez and Rehfeldt 2009), expressive language (Goldstein and Moussetis 1989), preference for items (Leaf et al. 2012; Singer-Dudek et al. 2011), and reading skills (Rehfeldt et al. 2003; Taylor et al. 2012). Bruzek and Thompson (2007) had young children watch their peers play. They found that simply watching peers play with previously non-preferred items may establish non-preferred items as preferred for young children. The change in preference resulted in those children playing with novel or less preferred items or activities in subsequent play sessions. This application of observational learning provides a simple procedure to increase play skills and may additionally increase the motivation to engage with new items or activities. In another example, Rehfeldt et al. (2003) employed an observational learning procedure with individuals with ASD and other developmental

disabilities. The individuals first observed peers being taught picture names, site words, and matching. Next, they demonstrated the same skills without direct instruction. The study demonstrated the generality of observational learning procedures to academic skills. The authors concluded that observational learning opportunities may be an economical and efficient method for providing instruction to individuals with developmental disabilities. Greer and Singer-Dudek (2008) utilized an observational learning intervention to increase conditioned reinforcers for young children. In this study the researchers evaluated if an item conditioned as a reinforcer through observation would effectively reinforce correct responses during academic instruction. Academic tasks included matching pictures and numbers, site word identification, and counting. Number of correct response across all participants increased, demonstrating the efficacy of observational learning procedures to condition items as reinforcers for academic tasks. In an extension of this research, Singer-Dudek et al. (2011) were also able to establish books as reinforcers for children in a preschool through observational learning. Lastly, observational learning procedures have been implemented across a variety of environments and activities. Settings for these interventions have included but are not limited to, general education classrooms, homes, individual work areas, and special education classrooms. Importantly, many of the interventions have involved educational settings.

Generality of observational learning: Observational learning has also helped to inform the validity of inclusive opportunities for individuals with ASD. We know from previous literature on best practice approaches to instruction for individuals with ASD that discrete trial instruction (DTI) is often the intervention of choice for establishing new skills (Smith 2001). Unfortunately, this type of intervention often fails to include the natural setting or ensure that individuals with ASD are learning from peers. One barrier to successful inclusion and instruction in the natural environment is the variability that may occur. This is no different for procedures which involve observational learning. Variability in a natural

environment may involve the inconsistency of the model, the immediacy or consistency of adult prompting, or the schedule of reinforcement. To counter these types of variability, many observational learning interventions have occurred outside of the natural environment with peer confederates who are trained to engage in a series of responses at a consistent rate. An important study, conducted by Brody et al. (1978), demonstrated that intermittent modeling was as effective as consistent modeling in an observational situation. This study involved typically developing children who had previously mastered the skill of learning through observation. Specifically, the authors of this study found no significant difference in skills learnt when the model occurred in 50% of opportunities, versus 100% of opportunities. These data have important implications for the utility of observational learning interventions with individuals with ASD. Educational teams should ensure that learners have the necessary repertoires to learn through observation and subsequently measure that learning through observation is happening in controlled environments. Once an observational learning repertoire is established, learning through observation should lead to the development of new skills for individuals with ASD.

Efficacy Information

The benefits of observational learning cannot be understated. At minimum, the benefits of observational learning to individuals with ASD include but are not limited to (1) reductions in adult directed instruction, (2) increased time with nondisabled peers, (3) increased learning opportunities, and (4) learning new skills (Werts et al. 1996).

Outcome Measurement

Experimental studies have demonstrated that individuals with ASD who participated in an observational learning intervention developed new skills. Individuals with ASD who were taught the core skills of observational learning

demonstrated a generalized observational repertoire across environments and skills. Importantly, observational learning interventions enhanced individual skill repertoires without direct instruction or reinforcement. The time to skill acquisition varied across studies and interventions. Also, individual modifications were necessary for some participants to acquire skills. A common theme among previous research was that outcomes were dependent on each individual having prerequisite skills described above (e.g., delayed imitation, consequence discrimination).

The effects of observational learning are measured through continuous or discontinuous data which describe the level of independent skills acquired. Additionally, the degree to which these skills generalize and maintain in the absence of observational opportunities are paramount for judging the outcome of observational learning interventions.

Qualifications of Treatment Providers

Although formal qualifications are not required to implement observational learning, professionals implementing observational learning should have educational and practical experience in Applied Behavior Analysis, Psychology, or Education.

Obsessive Desire for Sameness

John T. Danial

Psychological Studies in Education, University of California, Los Angeles, Los Angeles, CA, USA

Definition

Obsessive desire for sameness refers to an aspect of ritualistic and repetitive behaviors and patterns of interest observed in autism spectrum disorders (ASD). It is one criterion in diagnosing ASD and refers to the insistence that aspects of a person's environment (involving items or even people) remain the same in appearance, sequence, or context. Obsessive desire for sameness often results in a restricted range of activities, rigidity of behaviors, resistance to change, and insistence on performing idiosyncratic rituals and routines.

Obsessive-Compulsive Disorder (OCD)

Lawrence David Scahill

Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA

Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA
Department of Pediatrics, Emory University, Atlanta, GA, USA

Short Description or Definition

Obsessive-Compulsive Disorder (OCD): OCD is an anxiety disorder that is defined by the presence of recurring worries (obsessions) and/or repetitive behavior (compulsions). Obsessions and compulsions often occur together, but not in all cases, and

both are not required for the diagnosis. OCD is relatively common condition affecting 2–4% of adults, but less common in children. It appears to have a genetic component, but environmental factors also likely play a role.

Clinical Expression and Pathophysiology

The individual with OCD may describe intrusion of unwanted thoughts having to do with contamination, fears of harm coming to themselves or others in the family, and the strong urge to check possible sources of harm. In many such cases, the compulsive behavior that follows is related to the obsessional worry. For example, the patient who is fearful of contamination may become involved in excessive washing rituals. The patient who fears that harm may come to the self or to the family members may perform various checking behaviors to prevent that harm from occurring. In other cases, the link between the worry and behavior is less clear. For example, some patients may describe the need to carry out a repetitive ritual such as tapping or counting in order to prevent something bad from happening to themselves or others. In such cases, the ritualized behavior has no connection to the worry.

In some cases, the compulsive behaviors are performed without a clear cognition. For example, some individuals will say that they would feel deeply uncomfortable or unsettled if they do not complete a given ritual. This may be the repetition of a routine activity such as opening and closing a door or setting down an object on the table where it will have to be repeated certain number of times in order to achieve a sense of completion. In such cases, there is a need to achieve a physical sense of completion rather than to prevent harm.

Evaluation and Differential Diagnosis

There is interest in OCD because children and adults with autism often have repetitive behavior. The repetitive behavior in children and adults with autism, however, may not be the same as repetitive behavior in individuals with OCD.

For example, children with autism may insist on reading the same book over and over again, or watching the same video over and over again. This is a preferred behavior – i.e., a behavior that the person wants to do. The difficulty for the child and family emerges when the family tries to move the child away from the preferred activity to accomplish activities of daily living. Thus, there is a common feature of repetitive behavior, but in OCD, the repetitive behavior is unwanted and often motivated by the urge to prevent harm.

Treatment

Another potential difference in a repetitive behavior in OCD and the repetitive behavior in autism relates to the issue of anxiety. In individuals with OCD, the compulsive behavior is in fact being performed in order to reduce anxiety. That anxiety could come from fears of harm or contamination or other sources. As the anxiety about this fear increases, the compulsive behavior is performed and anxiety declines. The reduction in anxiety is powerful reinforcement for repeating the behavior. By contrast, anxiety reduction does not appear to be the driving force for repetitive behavior in children and adults with autism – though this possibility warrants careful assessment.

This question about the similarity or difference in repetitive behavior in autism versus OCD has implications for treatment. The SSRIs are commonly used for the treatment of OCD and are generally regarded as effective for the treatment of OCD. The use of SSRIs for the treatment of repetitive behavior in children with autism spectrum disorders has been disappointing (link to citalopram and fluoxetine).

Two studies have shown that the SSRIs are not effective in reducing repetitive behavior in children and adolescents with autism spectrum disorders. In one study, 149 children with autism spectrum disorders and moderate levels of repetitive behavior were treated with citalopram or placebo for 12 weeks. After 12 weeks of treatment, there was no difference in the overall improvement in those on citalopram versus those on placebo. In addition, in measures of a repetitive

behavior, there was no difference between citalopram and placebo groups. Another study involving 158 children with a new formulation of fluoxetine was also negative with no difference on a measure of repetitive behavior between fluoxetine and placebo.

Obstetrical Complications/ Risk Factors

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

A range of factors can increase the risk to the developing fetus during pregnancy and at the time of birth. These range from genetic abnormalities in the fetus, complications for the mother in carrying the child to term, and various environmental factors in utero – for example, exposure to alcohol. Although much interest has centered on possible issues of obstetrical risk in autism and although such factors can clearly impact on development of the child, data for children with autism have been somewhat lacking and/or difficult to interpret.

Historical Background

Kanner (1943) suggested that autism is a congenital condition. Recent work has confirmed a very strong genetic basis for autism while leaving open the possibility for the operation of nongenetic factors to some, although relatively to a much smaller, degree (Rutter 2005; Wing and Potter 2002). The early literature on this topic was reviewed by Tsai (1987) and others (e.g., Bryson et al. 1988; Levy et al. 1988; Lanzi et al. 1991; Levy 1991), with conflicting findings. Various difficulties in comparing studies were noted – these related to differences in approach and sample, comparison groups, and so forth. Issues of birth order are also important since obstetric complications differ in frequency based on birth order (this effect may reflect the issue of “stoppage rules” in autism (see Jones and Szatmari 1988)) and are more frequent among first-, fourth-, and later-born offspring in a sibship (Bakan 1971;

Thomson and Barron 1983). A further complication is posed by the fact that obstetrical problems might reflect the underlying genetic abnormality associated with autism, that is, they are best viewed as a consequence rather than a cause; this notion is supported by work that suggests that associations of obstetrical abnormalities and autism are weaker once adjustment is made for parity (Lord et al. 1991). So, for example, individuals with Down syndrome are more likely to have birth complications (Bolton et al. 1994).

Current Knowledge

The numerous possible alternative explanations for a relationship between autism and obstetrical complications have various implications. As noted by Bolton et al. (1997), each of the various hypotheses leads to various predictions. In their 1997 study, Bolton and colleagues evaluated obstetrical risks in families with a child with autism and families with a child with Down syndrome. Both groups had elevated obstetrical risk compared to unaffected siblings. Various factors have been associated with autism risk, but to date none has been sufficiently large in terms of effect to implicate a single factor in the pathogenesis of autism. In their 2011 meta-analysis, Gardener and colleagues reviewed over 60 perinatal and neonatal factors in data drawn from 40 studies. A number of factors that increased autism were identified (e.g., abnormal presentation, low birth weight, and birth injury, among others), but the authors concluded that there was insufficient evidence to implicate any one specific risk factor. Clearly a complication is the substantial methodological variation over the available studies.

Future Directions

As genes and possible brain mechanisms are identified, it may be possible to do a more thorough and hypothesis-guided examination of pre-, peri-, and neonatal risk factors in autism. At present, the influence of genetic factors appears to be strongly predominant.

Occipital Lobe

Kevin A. Pelphrey Harris
Child Study Center, Yale University School of
Medicine, New Haven, CT, USA

Synonyms

[Occipital lobes](#); [Visual cortex](#)

Definition

The occipital lobes are positioned at the back region of the cerebral cortex. The name “occipital” derives from the overlying occipital bone, which is named from the Latin occiput, or “back of the head.” Functionally, these regions of the cerebral cortex are the main centers for visual processing. For example, this area contains the primary visual cortex as well as an array of other, nearby visual regions specialized for different visual tasks, such as visuospatial processing, color discrimination, and motion perception.

State University, San José, CA, USA

Definition

Definition of Occupation

The term “occupation” is of special significance in the profession of occupational therapy. Occupations are those activities that surround us and occur at various times in our lives. The founders of the profession used the term “occupation” to denote the proper use of time including work, leisure, and self-care behaviors (Meyer 1922/1977). Occupations are those activities that are grouped together by a culture according to their purpose. These occupations may hold special significance or may seem ordinary. For example, the occupation of eating may seem to be an ordinary everyday occurrence, but during special holidays or events, the foods and accompanying environmental situations create a special significance and meaning. Even the everyday occupation of eating a meal may be disrupted when a child has severely limited acceptance of foods or rejects sitting at a table. In this situation, the seemingly ordinary occupation of eating a meal can become challenging. The term occupation serves as the core of the profession of occupational therapy and forms the perspective focused on health, well-being, and participation in those activities that are part of the culture (Kielhofner and Burke 1977). Occupations have been identified and classified into groups as follows (American Occupational Therapy Association [AOTA] 2008):

- Activities of Daily Living (ADLs): care of oneself including bathing, bowel and bladder management, toilet hygiene, dressing, eating including swallowing, self-feeding, functional mobility, sexual activity, personal hygiene, and grooming.

- **Instrumental Activities of Daily Living (IADLs):** activities seen in the care of home and community including care of others whether parents, siblings or children, care of pets, communication management by using equipment effectively, community mobility using both public and private transportation, financial management, health management and maintenance, home establishment and management, meal preparation and clean-up, safety and emergency maintenance, religious observance, and shopping.
- **Rest and Sleep:** these occupations include rest, sleep, and sleep preparation and participation and address the need to establish appropriate habits and routines for rest and sleep.
- **Education:** this occupation includes both formal educational participation and informal personal educational pursuits and participation.
- **Work:** includes activities related to both employment and volunteer work and includes employment interests and pursuits, employment seeking and acquisition skills, job performance, retirement preparation and adjustment, and volunteer exploration and participation.
- **Play:** includes play exploration and participation in various forms.
- **Leisure:** includes leisure exploration and participation in various forms.
- **Social Participation:** these occupations are “organized patterns of behavior that are characteristic and expected of an individual or a given position within a social system” (Mosey 1996, p. 340) and include participation at various levels such as the community, family, and with peers/friends.

These occupations are addressed within the profession of occupational therapy and serve as the foundation for practice. The complexity of occupations has been further studied in the field of occupational science.

Occupational Therapy

Occupational therapy is a client-centered profession frequently referred to as the “art and science

of helping people do the day-to-day activities that are important and meaningful to their health and well-being through engagement in valued occupations” (Crepeau et al. 2009, p. 217). The important characteristic of this profession is the collaboration with the client in the engagement in occupations. This profession includes three key elements of being client-centered, occupation-centered, and evidence-based.

The concept of being client-centered within the profession of occupational therapy recognizes the need for the client to be a collaborative member in the therapeutic process. This can assume many forms. A child may want to learn to play a video game where the family is concerned about that same child’s ability to interact with peers. The occupational therapy practitioner, using a client-centered approach, would incorporate both the use of video games and peer interaction to meet the client needs. In this situation, the client is not singularly the child but the child positioned within a family and society. Client-centered intervention can be used to meet the needs of individuals, organizations, and populations (AOTA 2008). Although most often client-centered is thought of in reference to a single individual, the profession of occupation therapy identifies the client from a broader perspective and services may be used to support organizations such as a school district where occupational therapy is provided to foster stress management through sensory strategies and sensory breaks for all children. Entire populations may also benefit from occupational therapy services such as addressing the occupational needs of homeless children.

The profession of occupational therapy is clearly linked with occupation-centered practice (Crepeau et al. 2009). The focus of intervention on helping a client become successful with day-to-day activities is the hallmark of occupational therapy. This is illustrated when an occupational therapist is working with a child to master brushing teeth or use of utensils during a meal. Within a school setting, this same child may benefit from occupational therapy services focused on peer interaction on the playground or

in the classroom when this child is expected to complete a written assignment.

The profession, from its very beginnings, has sought to provide evidence of the effectiveness of intervention focused on engagement in occupations. To practice evidence-based occupational therapy requires the practitioner to examine three factors (Crepeau et al. 2009). First, the occupational therapy practitioner must know how to “access, evaluate, and interpret relevant research” (p. 219). This requires knowledge of current publications and the type of research literature available. The second element the occupational therapist must address is the collection of appropriate data to support recommended interventions. The final factor within evidence-based occupational therapy requires the practitioner to disseminate this information to the client, so the client can make an informed decision regarding the recommended intervention.

The focus of occupational therapy intervention is not merely on addressing client deficits, although that is within the practice of the profession. Occupational therapy intervention has identified five approaches as follows (AOTA 2008; Dunn et al. 1998):

- Create/promote (health promotion): a disability is not assumed, and intervention is designed to provide an enriched experience, an example can be seen in health promotion activities for adults or children to develop healthy habits for leisure and play.
- Establish, restore, or remediate: intervention is focused on developing the skills or abilities needed for participation in occupations; examples can be seen when an occupational therapist helps a child develop the skills needed to play with peers or when an occupational therapist helps a child develop the motor memory needed for handwriting.
- Maintain: this intervention is designed to preserve client capacities to engage in occupations and is provided to avoid a decline in functional abilities; an example can be seen when an occupational therapist provides organizers for a child’s backpack at the beginning of each school year.
- Modify, compensate, or adapt: this intervention is designed to change the environment,

situation, or setting to allow the client to participate in the occupation; examples can be seen when an occupational therapist suggests use of voice-activated software for a student who has difficulties completing written assignments or the use of a seating cushion for a child who needs movement within a classroom setting.

- Prevent/disability prevention: this approach is designed to prevent problems, and examples can be seen when an occupational therapist provides soft-cushioned pencil grips to the entire classroom of children before they begin to write or the use of a slant board in classrooms to help children assume an upright posture during written assignments.

These forms of occupational therapy intervention reflect the diversity of services provided. The profession has a wealth of knowledge that extends beyond working only on a specified disabling condition and includes a wide range of clients with occupational needs.

Historical Background

History

Occupational therapy as a profession started in 1917, but the foundations for this profession dedicated to occupational engagement were established far earlier than that date. Prior to the 1800s, individuals who displayed mental health disorders were treated with approaches meant to control their behavior instead of treat the behavior. Those with mental health problems were viewed as dangerous and incurable. The use of purgatives, emetics, beatings, and bloodletting was used to weaken the individual displaying unacceptable behaviors. With the advent of moral treatment in the beginning of the nineteenth century, those who displayed mental health problems were viewed as needing humane intervention instead of punishment. Asylums were established to provide treatment for those with mental health problems and the value of engaging in occupations was established. The treatment for those with mental health disorders often included engagement in various occupations such as gardening, sewing, or working in a shop.

The formal beginning of the profession of occupational therapy occurred in Clifton Springs, New York, USA, on March 17, 1917, with the foundation of the National Society for the Promotion of Occupational Therapy (NSPOT). This society was formed by individuals from varied professional backgrounds, reflecting the complexity of occupational therapy. A psychiatrist, William Dutton, considered the father of the profession, and Eleanor Clark Slagle, a welfare worker, considered the mother of the profession, along with architects, nurses, and teachers established the society. Adolf Meyer, a psychobiologist, was instrumental during the initial formation of the profession and published “The Philosophy of Occupational Therapy” in 1922, describing the need for occupational engagement with an understanding of the role of time and temporality as part of the profession. The use of habit training was a core element to the profession of occupational therapy and addressed the temporality described by Meyer. Another core element of the profession is energy conservation. One of the founding members of the NSPOT was an architect by the name of George Barton. He was a leading proponent of “efficiency techniques” and was instrumental in having the concepts of efficiency techniques included in the profession.

World War I (WWI) brought about an expansion in the profession of occupational therapy. Initially formed to provide intervention for those who had mental health problems, the needs of injured soldiers from WWI pressed the profession to develop quickly. The United States (US) military sought the assistance from NSPOT to recruit and train 1,200 “reconstruction aides” to meet the needs of wounded and injured soldiers including those suffering from “shell shock.” The efforts of NSPOT and the reconstruction aides were praised by the US Surgeon General’s office for their service to WWI veterans. In Canada, a similar growth in the need for occupational therapists was seen during WWI. They were identified as “ward aides” or “occupation aides” in Canada and served returning veterans.

Following WWI, the profession of occupational therapy established training standards and criteria for practitioners of occupational therapy in the USA. In 1921, the NSPOT changed its name to

the American Occupational Therapy Association (AOTA) and in 1931 created the first national registry of qualified occupational therapy practitioners. The profession continued to advance and refine its training but more slowly during the Great Depression. With the beginning of World War II (WWII), the profession of occupational therapy saw a dramatic increased demand for trained professions and the number of educational programs expanded. From 1941 to 1946, the number of trained occupational therapy professionals in the USA doubled to meet the needs of WWII veterans. Canada experienced similar increased demand, and Canadian occupational therapists were recruited to serve in Britain to meet the needs of veterans. The educational training of occupational therapists expanded to include activities of daily living in addition to the use of therapeutic activities.

Global Occupational Therapy

The profession of occupational therapy continued to expand, and in 1952, the World Federation of Occupational Therapy (WFOT) was formed. Representatives from the USA, Canada, England, Scotland, South Africa, Sweden, New Zealand, Australia, Israel, India, and Denmark initiated the organization. WFOT was admitted into official relations with the World Health Organization (WHO) in 1959 and was recognized as a non-governmental organization (NGO) by the United Nations (UN) in 1963. The purpose of this organization is to act as the international organization for the promotion of the profession. Included in WFOT’s initial objectives was the education and training of occupational therapists with the advancement of standards of practice. There are currently 57 member organizations of WFOT.

Current Knowledge

Educational Requirements for Occupational Therapy Practitioners

The education of an occupational therapy practitioner includes coursework in the psychological, psychosocial, medical, biological, social behavioral, and occupational sciences. Within the USA, there are two levels of occupational therapy

practitioners, the occupational therapist and an occupational therapy assistant. The entry-level occupational therapist is educated at the minimum with a master's degree of 5–6 years of college with thorough preparation in occupational therapy theory and practice, research, internships, and successful passing of the national registry examination. The completion of the master's degree is not sufficient to practice occupational therapy. The occupational therapy postbaccalaureate graduate must also pass the rigorous national registry examination to be allowed to practice as an occupational therapist. Once a graduate has passed this exam, the designation of Occupational Therapist, Registered (OTR) can be used. Most states within the USA also require licensure, and the designation of OTR/L is frequently used to designate a practitioner who is registered and licensed to practice occupational therapy.

The training at the assistant level is typically completed within a 2-year period of college work in the areas of psychological, psychosocial, medical, biological, social behavioral, and occupational sciences. The student pursuing an occupational therapy assistant degree must also complete coursework in occupational therapy practice and internships prior to sitting for the national certification examination. A graduate from an occupational therapy assistant program who has successfully completed the national examination is eligible to use the designation of Certified Occupational Therapy Assistant (COTA).

There are several programs within the USA that offer entry-level occupational therapy degrees at the doctoral level using the designation of Occupational Therapy Doctorate (OTD). Student enrolled in OTD program must also complete a course of study that includes psychological, psychosocial, medical, biological, social behavioral, and occupational sciences. A thorough preparation in occupational therapy theory and practice, research, internships, and successful passing of the national registry examination is included in this course of study over 6–7 years of college. The OTD program often allows further study in a specific area of

occupational therapy or occupational science, but the graduate with an entry-level OTD degree is still required to complete internships and successfully pass the national registration examination before being able to practice as an occupational therapist.

Advanced degrees in occupational therapy are also offered at the OTD level where the practitioner has already completed the entry-level requirements and is seeking an advanced degree. The field of occupational science, the science involved with the study of occupations, includes PhD preparation to further the knowledge of occupations.

Occupational therapy practitioners may demonstrate a level of knowledge and competence beyond entry level through additional certifications and degrees. An example is seen with the AOTA specialty and board certification programs (AOTA 2011). The specialty certification program provides both levels of practitioners to demonstrate advanced skills in specific areas of practice. Areas included in the specialty certification are the following: Driving and Community Mobility, Environmental Modification, Feeding, Eating, and Swallowing, and Low Vision. Board certification identifies occupational therapists that have achieved advanced knowledge and competence in large domains of practice and includes Pediatrics, Physical Rehabilitation, Gerontology, and Mental Health.

Conclusion

The profession of occupational therapy continues to change to meet the occupational needs of clients worldwide. In the USA, the profession of occupational therapy will reach its 100-year mark in 2017 and the Centennial Vision of AOTA articulates this concept of meeting the occupational needs of all clients:

We envision that occupational therapy is a powerful, widely recognized, science-driven, and evidence-based profession with a globally connected and diverse workforce meeting society's occupational needs. (AOTA 2006).

Olanzapine

Brett Yamane¹, L. Lee Carlisle² and Bryan King³

¹Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, USA

²Division of Child and Adolescent Psychiatry, Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, USA

³Department of Psychiatry and Behavioral Sciences and Seattle Children's Hospital, University of Washington, Seattle, WA, USA

Definition

Olanzapine is a second-generation antipsychotic (SGA) with a greater 5HT_{2A}/D₂ dopamine receptor antagonist ratio as compared to a first-generation antipsychotic (FGA). As such, SGAs are purported to have a more benign side-effect profile, with a lower risk for causing extrapyramidal side effects (EPS) and tardive dyskinesia associated with long-term exposure.

Historical Background

Olanzapine is an SGA originally introduced for use in adults with psychosis. It is structurally similar to clozapine but without the propensity toward agranulocytosis, has relatively lower rates of anticholinergic side effects, and has lower risk for drug interactions. When compared to FGAs, olanzapine offers a lower risk of EPS. Based on the promising clinical findings in adults, investigators became interested in olanzapine's effects in youth.

Studies have emerged evaluating the efficacy and tolerability of olanzapine in children and

adolescents. One study of adolescents with bipolar mania, randomized to either olanzapine or placebo, demonstrated significantly improved response and remission criteria in the treatment group (Tohen et al. 2007). A schizophrenia study of adolescents randomized to olanzapine demonstrated improvement in all primary outcome measures including the Clinical Global Impression Scale-Severity of Illness, Brief Psychiatric Rating Scale for Children, and Positive and Negative Syndrome Scale (PANSS) compared with placebo (Kryzhanovskaya et al. 2009). In the Treatment of Early Onset Schizophrenia Spectrum Disorders Study (TEOSS), patients were randomized to olanzapine, risperidone, molindone, or placebo with no significant differences in response rates between active treatment groups (Sikich et al. 2008). What was consistent among the three randomized studies was the olanzapine arms consistently demonstrated statistically significant weight gain and changes in metabolic indices. In TEOSS, olanzapine was discontinued when interim data showed a greater increase in weight than with either risperidone or molindone without greater efficacy. An open-label study of five hospitalized preadolescent children, administered with olanzapine for bipolar disorder, psychosis NOS, schizophrenia, and ADHD, demonstrated either adverse effects or lack of clinically significant therapeutic responses leading to its being discontinued in all patients (Krishnamoorthy and King 1998). It is due to these findings that olanzapine is largely administered as a second-line or third-line treatment for schizophrenia in pediatric patients.

There is a dearth of data on prescribing rates of olanzapine in children and adolescents, but Constantine and Tandon describe changing trends in antipsychotic use in Florida (Constantine and Tandon 2008). They refer to the conclusions of both the Consensus Statement of the American Diabetes and the American Psychiatric Associations in February of 2004, including olanzapine and clozapine being associated with the greatest risk of weight gain, diabetes, and dyslipidemia (American Diabetes Association et al. 2004). By December of 2005, olanzapine was the least prescribed SGA in pediatric patients in Florida's

Medicaid program. In another study of privately insured children, risperidone accounted for 74.3% of antipsychotic prescriptions, followed by aripiprazole (13.9%), and ziprasidone and paliperidone both prescribed in less than 1% of cases (Olfson et al. 2010).

While the Food and Drug Administration has approved risperidone and aripiprazole for the treatment of symptoms associated with autism, other medications are often used "off-label" to target problem behaviors. Haloperidol has been demonstrated in placebo-controlled studies to be effective in treating these behaviors in children and adolescents (Anderson et al. 1984; Campbell et al. 1978; Cohen et al. 1980; Naruse et al. 1982). Its use is now limited due to the incidence of side effects including sedation, EPS, and tardive dyskinesias (Campbell et al. 1978, 1997). Therefore, SGAs have largely replaced FGAs to improve disruptive behaviors associated with ASDs (Hollander et al. 2006; McCracken et al. 2002).

In 1997, the National Institute of Mental Health funded five university-affiliated medical centers with expertise in the treatment of autism to constitute the Research Units on Pediatric Psychopharmacology (RUPP) autism network (King and Bostic 2006; McDougale et al. 2008). Because of a number of case reports describing the potential benefit of risperidone in children with autism and other developmental disabilities, the RUPP network selected risperidone for a multicenter trial and found that it improved aggression, hyperactivity, and irritability over 8 weeks (King and Bostic 2006; McCracken et al. 2002). Since the initial RUPP risperidone trial, there have been a number of other randomized, double-blind, placebo-controlled trials evaluating risperidone, but much less research has focused on olanzapine in children with ASD (Nagaraj et al. 2006; Shea et al. 2004).

Current Knowledge

Several case reports have been published regarding olanzapine use in children with ASD. In one case, a 10-year-old boy with bipolar disorder, autism, and mental retardation was switched

from thioridazine and fenfluramine to olanzapine and lithium and demonstrated a decrease in both aggression and repetitive behaviors (Horrigan et al. 1997). An 8-year-old boy with autism and hyperactivity and disruptive behaviors who had failed multiple drug trials was given a trial of olanzapine which reportedly decreased his hyperactivity and resolved his aggression (Malek-Ahmadi and Simonds 1998). London reported a case of olanzapine-induced mania in a child with PDD (London 1998).

In an initial open-label pilot study examining safety and tolerability of olanzapine in children, adolescents, and adults with PDDs (Potenza et al. 1999), eight patients were given treatment over 12 weeks. The mean dose at the end of the study was 7.8 mg/day. Seven patients completed the study, and six were considered either “much improved” or “very much improved” on the Clinical Global Impression-Improvement Scale or CGI-I ($p < 0.001$). The Vineland Adaptive Behavior Scale and Maladaptive Behavior Subscales (VMBS) captured significant improvements from baseline in temper tantrums, impulsivity, anxiety, and social withdrawal ($p < 0.001$). Rocking, property destruction, and inappropriate sexual behavior were also significantly decreased after olanzapine ($p < 0.005$). Significant improvement in overall symptoms with olanzapine was also reflected by Ritvo-Freeman Real Life Rating Scale overall scores ($p < 0.001$). No significant difference was noted in repetitive behaviors over the duration of the study. Significant weight gain was seen in six of the eight patients during the 12-week trial ($p = 0.008$). There were no cases of EPS.

In an open-label 6-week study, 12 children (mean age 7.8 years) with ASD were randomized to either olanzapine or haloperidol (Malone et al. 2001). The mean doses for haloperidol were 1.4 mg/day and 7.9 mg/day of olanzapine. The primary outcome measure was the CGI scale, with a secondary outcome based on the Children’s Psychiatric Rating Scale (CPRS). Five of the six subjects in the olanzapine group were considered responders on the CGI, either “much improved” or “very much improved,” compared to three of the six in the haloperidol group. There was no

statistically significant difference between groups. The CPRS autism factor assesses for social withdrawal, rhythmic motion/stereotypy, abnormal object relations, underproductive speech, and unspontaneous relation to the examiner. For the CPRS autism factor, both groups demonstrated significance in improvement from baseline to endpoint ($p = 0.0008$). Only the olanzapine group demonstrated significance in decreasing the anger/uncooperativeness and hyperactivity CPRS factors. The most common side effects included time-limited sedation and weight gain. All but one child taking haloperidol gained weight, and the olanzapine group demonstrated significantly more weight gain than the haloperidol group ($p < 0.04$). All six olanzapine children gained over 5 lb., compared with two in the comparator group. There was no EPS in the olanzapine group. The authors concluded that olanzapine appeared to be a safe alternative to haloperidol for short-term treatment of behavior symptoms in PDD.

A 3-month open-label study was performed in order to assess the effect of olanzapine on communication in children with PDD (Kemner et al. 2002). Twenty-five children between the ages of 6–16 (mean = 11.2) years with either a diagnosis of autism or PDD NOS were followed and evaluated. The mean maximum dose at the end of the study was 10.7 mg/day. Psychometric measures included the CGI, Aberrant Behavior Checklist, and TARGET (a clinician-generated checklist consisting of five target symptoms chosen by parents). Communication skills were assessed in children with fluent speech ($n = 20$) via behavioral analyses of a playroom session. The results of this study showed significant improvements on TARGET and three subscales of the Aberrant Behavior Checklist for irritability, hyperactivity, and inappropriate speech. Based on CGI-I, only three children could be considered responders. Twelve children were considered significantly less ill after olanzapine based on the CGI-severity score. These results did not replicate previous studies demonstrating much or very much improvement on CGI-I after treatment with olanzapine where the majority of children showed minor improvement. Adverse events included

weight gain (average 4.7 kg), increased appetite, and decreased strength, and three children developed EPS that resolved after lowering the dose of olanzapine.

A case series looking at the long-term effects of olanzapine was performed by Stavrakaki, Antochi, and Emery (2004). Seven subjects (ages 8–52) with PDD were monitored over 17 months for improvements in the CGI scale and Global Assessment of Function (GAF). Five of the seven had diagnoses of autism and two with PDD NOS. The mean dose of olanzapine was 7.1 mg/day. In this series, only two of the cases were children. The two boys were also on additional medication: risperidone, methylphenidate, and clonidine in an 8-year-old and dextroamphetamine in an 11-year-old. There was a significant increase in GAF scores from 37.7 pretreatment to 70.7 at end of study ($p < 0.0001$). By week 52, one subject had “improved,” three subjects were “much improved,” and three other subjects were “very much improved,” making six responders. The most common side effect was sedation, and one patient had a seizure not considered attributable to olanzapine. Interestingly, there was no significant weight gain ($p = 0.97$), but the authors note that subjects were monitored closely and treated with dietary and behavioral interventions which may have accounted for this finding.

The first and only randomized, double-blind, placebo-controlled study of olanzapine in PDD was an 8-week study conducted by Hollander et al. (2006). Six of 11 children (ages 6–14 years) were diagnosed with autism. Dosages of olanzapine were based on weight and ranged from 7.5 to 12.5 mg/day. The primary outcome measure was the clinician-rated CGI-I score at 8 weeks, and secondary outcome measures included the compulsion subscale of the Children’s Yale-Brown Obsessive Compulsive Scale (CY-BOCS) and the Overt Aggression Scale-Modified (OAS-M) irritability and aggression subscales. There was a nonsignificant improvement in the primary outcome of the treatment group averaging 4.0–2.25 ($+/-1.26$) versus the control group 4.0–3.5 ($+/-1.0$). Three of the six in the treatment group were responders, and one out of five placebo subjects was a responder (50%

vs. 20%). There were no significant changes noted on other outcome measures for irritability or aggression. The subjects receiving olanzapine gained more weight than controls, averaging 7.5 lbs. versus 1.5 lbs. in the control group. Four of the six olanzapine-treated subjects (66.6%) had more than 7% weight gain compared to one of five control subjects (20%). Weight gain and sedation were the most common side effects in the treatment group. There were no reported extrapyramidal symptoms associated with olanzapine.

Children have been shown to be more susceptible than adults to the side effects of FGAs and SGAs (Sikich et al. 2004). In a randomized controlled trial of 40 youth with psychotic disorders, haloperidol, risperidone, and olanzapine were compared. EPS was found in 67% of the haloperidol arm versus 56% and 53% of the risperidone and olanzapine arms, respectively. Those on haloperidol reported more severe EPS. Despite the greater risk of side effects, antipsychotics are increasingly being used in children and adolescents (Olfson et al. 2006).

In regard to long-term side effects, a meta-analysis by Correll and Kane looked at the use of SGAs for various psychotic and nonpsychotic diagnoses, including ASD. Ten studies were evaluated to assess the 1-year risk of tardive dyskinesia (TD) in children under 18 years old. There were 783 youth who received risperidone ($n = 737$), quetiapine ($n = 27$), or olanzapine ($n = 19$). Of these, after 3 years of treatment, there were three new cases of TD diagnosed. One-year TD rates are relatively low (annualized rate 0.42%), but the data was limited for SGAs other than risperidone, and many children are treated with higher doses of SGAs for longer durations which may lead to a greater TD risk not demonstrated in this study (Correll and Kane 2007).

Future Directions

With only a limited amount of data available regarding the use of olanzapine in the treatment of ASD, its use remains primarily empirical. On the other hand, there is extensive data concerning children with other psychiatric disorders treated with olanzapine

that warrants concern about side effects, specifically metabolic effects and weight gain. In the Sikich study, subjects in all treatment arms gained significant weight above normal growth, but olanzapine was the highest, followed by risperidone, then haloperidol (Sikich et al. 2004).

It remains crucial to continue reviewing emerging data regarding SGAs and their associated risks, particularly weight gain. At this time, given the state of the evidence, alternative SGAs should be considered prior to olanzapine for children with autism spectrum disorders given the chronicity of the disease and prolonged need for antipsychotic medications.

Omission Training

Vicki Madaus Knapp¹ and David McAdam²

¹Applied Behavior Analysis (ABA) Program, Daemen College, Amherst, NY, USA

²Department of Pediatrics, University of Rochester Medical Center, Rochester, NY, USA

Synonyms

Negative punishment; Type II punishment

Definition

Omission training is a behavior-analytic term that refers to a form of punishment in which an event is withdrawn contingent on the occurrence of a target behavior (e.g., property destruction, aggression toward other people). In the behavior-analytic literature, omission training typically is considered to be negative or Type II punishment. Everyday examples of omission training include loss of privileges (e.g., having to leave the zoo early contingent on hitting your mom, loss of one's driver's license for getting too many speeding tickets). Time-out and response cost are the two most commonly used forms of omission training. Time-out is the removal of a positive event contingent on the occurrence of a challenging behavior. Response-cost is the removal of a specified amount of a positive reinforcer contingent on the occurrence of a challenging behavior (see ► [“Time-out”](#) and ► [“Response Cost”](#) entries for additional details).

[Age of onset](#); [Age of recognition](#)

Definition

In his original report of the autistic syndrome, Kanner speculated that the condition he described was congenital, i.e., that the children were born with it (Kanner 1943). Parental report of age of onset was one of the major significant variables noted to separate childhood autism from other forms of severe disturbance – notably childhood schizophrenia (Kolvin 1971; Rutter 1972). Early onset was also a feature included in some of the first more operationalized definitions of the disorder (e.g., American Psychiatric Association [APA] 1980; Rutter 1972).

Subsequent work has generally supported the notion that autism is an early-onset disorder present at birth or becoming apparent in the first year of life. Although the term onset is typically used, in fact recognition is a more appropriate term since various factors might complicate recognition of the disorder, e.g., parental sophistication, education, denial, and so forth (Chawarska et al. 2007; Volkmar et al. 1985). A small body of work has begun to focus on direction observation, e.g., of high-risk samples followed over time, home videotapes, and so forth, and these frequently suggest that subtler difficulties may precede the more obvious ones that can give rise to parental concern (Chawarska et al. 2007; Osterling and Dawson 1994; Werner and Dawson 2005; Werner et al. 2000).

Most studies reliant on parent report suggest that parents are typically worried in the first or second year of life about their child's development. For example, Short and Schopler (1988) examined reported age of onset in a large group of cases at Division TEACCH and noted that in 76% of cases, parents were worried by age 2. In the DSM-IV field trial for autism, about 90% of parents had experienced concern by age 2 years (Volkmar et al. 1994). Recognition can be influenced by several factors including parental sophistication (or denial), severity of associated developmental delay, and/or autistic symptoms (Rogers and DiLalla 1990; Short and Schopler 1988).

With respect to onset, it should also be noted that in about 20–25% of cases, parents report a pattern of regression as part of the onset of autism (Rogers and DiLalla 1990). This issue remains somewhat controversial and poorly understood since frequently studies have relied primarily on parental report, with little attention to aspects of either reliability or exploration of the nature of the regression reported.

Sometimes, the issue is more one of a failure of development to progress, and at other times parents note a regression but in the context of a pattern of ongoing delay. The most noteworthy pattern, i.e., of marked developmental regression in the face of clearly normal development previously, is the least common but also probably the most important for research (Siperstein and Volkmar 2004).

Operant Behavior

Meghan Brahm

Department of Special Education, Southern
Connecticut State University, New Haven, CT,
USA

Definition

Operant behavior is defined as voluntary behavior which is influenced by the consequences that follow it (Cooper et al. 2019).

The term “operant” was coined by B.F. Skinner and used to reflect the idea that an organism “operates” on its environment when engaged in operant behavior. In his early works, Skinner studied the behavior of rats and pigeons under laboratory settings to gain a controlled understanding of the principles of operant behavior (Skinner 1938). Once he established a foundational understanding, he evaluated his findings further, and within human populations. Through this work, he identified operant behavior as well as the process of operant conditioning (Pear and Eldridge 1984).

Operant behavior is best understood in the context of what is called the three-term contingency or the antecedents, behavior, and consequences which comprise an instance of operant behavior. Antecedents refer to the stimuli which are present in the environment directly before an instance of behavior. Behavior is the phenomena of interest, or the response of an organism to said antecedents. Consequences refer to the stimulus change which occurs after behavior. Understanding consequences is critical to examining operant behavior. It is well understood that the consequences which follow a behavior make it more or less likely that the behavior will occur again in the future (Cooper et al. 2019). That is to say, a reinforcing consequence will increase the future frequency of an operant behavior, and a punishing consequence will decrease its future frequency (Cooper et al. 2019).

The decades of research and applied work on operant behavior and operant conditioning have

been critical in the development of evidenced-based interventions to support individuals with autism spectrum disorder (ASD; Wolf et al. 1963). As the science of applied behaviour analysis predominantly focuses on operant behaviors, interventions which have emerged from the field aim to understand the operant conditioning process and change consequences to alter behavior (Sturmey et al. 2020). Interventions which aim to aid in meaningful behavior change for individuals with ASD and related disorders, such as functional communication training, teaching self-help, social and leisure skills, and supports for maladaptive behavior, all focus specifically on operant behavior (Sturmey et al. 2020). Hence, operant behaviors are an essential area of study as they relate to ASD.

Operant Conditioning

Dorrey Sproatt¹ and Anahita Navab²

¹Psychological Studies in Education, University of California, Los Angeles, CA, USA

²Department of Psychology, University of California, Los Angeles, CA, USA

Synonyms

[Instrumental conditioning](#); [Instrumental learning](#)

Definition

A process of learning in which a behavior's consequence affects the future occurrence of that behavior. B. F. Skinner (1953) derived the principles of operant conditioning from Thorndike's "law of effect," which suggests that a behavior producing a favorable or *satisfying* outcome is more likely to reoccur, while a behavior producing an unfavorable or *discomforting* outcome is more likely to decrease in frequency (Thorndike 1911).

Skinner's experimental work focused on the effects of different schedules on the rates of operant responses made by rats and pigeons (Skinner 1953). His work revealed that the frequency of a behavior could be increased through reinforcement. Two types of reinforcement include positive reinforcement, the giving of a rewarding stimulus following a behavior, and negative reinforcement, the removal of an aversive stimulus following a behavior.

Similarly, the frequency of a behavior can be decreased through punishment. Positive punishment is the giving of an aversive stimulus following a behavior, and negative punishment is the removal of a rewarding stimulus following a behavior. The frequency of behavior can also be decreased through extinction, the discontinuation of the behavior's reinforcer (Skinner 1953).

Alternatively, a new behavior can be produced by means of shaping, the reinforcement of

increasingly accurate approximations at the desired behavior.

Operant conditioning has played an integral role in the development of effective interventions targeting the modification of behavior, specifically operant language training, in individuals with autism spectrum disorder (ASD) (Hewett 1965; Lovaas et al. 1966).

Additionally, applied behavior analysis (ABA) or the “Lovaas technique,” introduced by Ivar Lovaas, has validated the efficacy of operant conditioning principles in the treatment of individuals with ASD (Lovaas 1987).

Optimal Outcome

Katherine Tyson¹ and Deborah Fein²

¹Chapel Hill Pediatric Psychology, P.A., Chapel Hill, NC, USA

²Department of Psychological Sciences, University of Connecticut, Storrs, CT, USA

A small percentage of individuals with autism spectrum disorders (ASDs) may go on to lose core symptoms of the diagnosis and achieve “optimal outcomes.” Helt et al. (2008) defined an individual with an optimal outcome as having a history of an ASD diagnosis, demonstrating average or above average academic and adaptive functioning, receiving minimal special education supports specific to autism symptoms, and not meeting criteria for a diagnosis of ASD diagnosis as determined by administration of the Autism Diagnostic Observation Schedule (ADOS).

It should be noted that losing an ASD diagnosis is not the only good outcome that can be achieved. Finding strengths in individual children with ASD that give them satisfaction and can be nurtured, maximizing their ability to communicate and have relationships with others, and successfully treating comorbid sources of distress (e.g., anxiety, depression) are other criteria for good outcomes. In fact, comorbid conditions such as anxiety and depression can persist in individuals who lose the ASD diagnosis and can be more distressing than the ASD symptoms themselves.

Lovaas (1987) pioneered the study of “recovery” from ASD when he reported strong cognitive and academic outcomes in a small sample of individuals with high-functioning ASD following early, intensive behavioral intervention. Since Lovaas’ study, a number of researchers have carried out further studies of outcome from ASD, including losing the diagnosis, with stronger experimental designs and more comprehensive measures of outcome (e.g., Fein et al. 2013; Salows and Graupner 2005).

Helt et al. (2008) estimate that between 3% and 25% of children diagnosed with ASD lose the diagnosis and exhibit average cognitive, adaptive, and social abilities. Helt and colleagues argue that misdiagnosis of ASD does not explain this phenomenon. The authors suggest that this outcome from ASD could be limited to certain subsets of ASD and is likely strongly tied to early detection and treatment, characteristics of the child (e.g., cognitive abilities), and maturation.

Recent studies have examined specific characteristics of children and adolescents with optimal outcomes using a variety of measures of psychological and neuropsychological functioning, as well as brain imaging. A comprehensive study by Fein and colleagues (summarized in Fein et al. 2013) indicated that a group of children and teenagers with optimal outcomes had similar academic, executive functioning, language, and social skills in comparison to typically developing study participants. When compared to typically developing peers, the optimal outcome participants did display some subtle differences in their pragmatic language. They also presented with a higher incidence of psychiatric concerns than typically developing controls, particularly symptoms of attention-deficit/hyperactivity disorder and specific phobias (Orinstein et al. 2015).

An important longitudinal study by Anderson et al. (2014) found that about 10% of their sample had “very positive outcome,” with a definition similar to Fein et al.’s definition of “optimal outcome”; they found that remitting of repetitive behaviors between ages 2 and 3 with intervention was the strongest predictor of this outcome.

Eigsti et al. (2016) have also explored ways in which brain networks responsible for language may differ for individuals with optimal outcomes. Findings indicated largely similar patterns of activation for individuals with optimal outcomes compared to those with ASD across several brain regions. However, the optimal outcome group also demonstrated “compensatory” activation in numerous regions, differing from both a typically developing control group and the ASD group. Results suggest that early treatment and

learning experiences may result in normalized language performance for optimal outcome individuals but that differing brain activity may underlie these observable behavioral similarities in language processing.

Further research is needed to understand the nature of differences between individuals with “optimal outcomes” and those with other developmental trajectories. Research suggests that intensive early intervention, specifically applied behavior analysis approaches to therapy, may contribute to better outcomes in ASD (Fein et al. 2013; Orinstein et al. 2015).

Oral Sensitivity

Allison Bean Ellawadi
Speech and Hearing Science, The Ohio State University, Columbus, OH, USA

Definition

Oral sensitivity is defined as an atypical response to oral stimulation. Atypical responses include hyporeactive responses, hyperreactive responses, or sensory defensiveness. Hyporeactive responses are characterized by a diminished response to sensory input. Individuals who are hyporeactive to stimulation in the oral and pharyngeal regions may have delayed triggering of the swallowing mechanism, putting them at risk for aspiration. Hyperreactive responses are characterized by an excessive reaction to sensory input (Arvedson and Brodsky 2002). Hyperreactive responses to oral stimulation may develop into a conditioned facial defensiveness. This is because individuals may come to associate discomfort with the feeding process and develop a conditioned avoidance of food and other oral and facial stimulation (Arvedson and Brodsky 2002; Dodrill et al. 2004). Oral sensory defensiveness is characterized by an emotional

response to sensory input. Individuals who are orally defensive may take only a limited variety of tastes and textures orally and frequently refuse food. Treatment of oral sensitivity problems may involve adaptation of the sensory environment, implementation of specific techniques, and/or modifications of sensory qualities of food or feeding utensils (Arvedson and Brodsky 2002).

Psychology, University of Rochester, Rochester,
NY, USA

Synonyms

[Facial imitation](#); [Oral-motor imitation](#); [Orofacial imitation](#)

Definition

Oral-facial imitation refers to the imitation of others' actions that specifically involve the mouth or face. It has been extensively researched in infants, and is thought to be the earliest form of

imitation present in typical development. There is evidence that neonates possess the capacity to imitate some oral-facial movements. This has led to theories positing that this type of early imitation plays a central role in the development of interpersonal skills, possibly via the creation of shared representations of the self and others. Research also suggests a relationship between oral-facial imitation skills and speech development. In older individuals, the focus of oral-facial imitation research is often on the imitation of facial expressions, particularly those conveying emotion. Oral-facial imitation should be distinguished from oral-facial mimicry or contagion. Whereas mimicry and contagion are considered automatic matching responses to others, imitation is thought to be volitional. There is some debate over whether neonatal oral-facial responses are automatic or volitional, but it is clear that older children and adults display behaviors of both types. A number of studies have implicated oral-facial imitation as a specific area of impairment in autism spectrum disorder (ASD). Given that oral-facial imitation abilities may be important for language development and for social-emotional reciprocity and learning, difficulties within this area could partially underlie the social-communicative symptoms associated with ASD.

Oral-Motor Apraxia

Allison Bean Ellawadi
Speech and Hearing Science, The Ohio State
University, Columbus, OH, USA

Synonyms

[Nonverbal oral apraxia](#)

Definition

Oral-motor apraxia is the inability to volitionally sequence oral movements of the speech structure for nonspeech tasks in the absence of neuromuscular deficits such as paralysis or muscle weakness (Zemlin 1998). Patients with oral-motor apraxia demonstrate off-target effortful groping for correct movements involving the speech structure (e.g., clicking the tongue, licking the lips, whistling), or inconsistent trial-and-error attempts. Spontaneous and reflexive movements, such as swallowing while eating and smiling at a joke, are not affected (Freed 2000). Oral-motor apraxia often occurs in conjunction with apraxia of speech, although there is not a one-to-one correspondence. Either apraxia may exist in the absence of the other (Duffy 1995).

Oral-Motor Skills

Allison Bean Ellawadi
Speech and Hearing Science, The Ohio State
University, Columbus, OH, USA

Definition

Oral-motor skills refer to the movement of the muscles of the face and oral area (e.g., mouth, jaw, lips, tongue, soft palate). These skills are influenced by muscle tone, muscle strength, range of motion, speed, coordination, and dissociation (the ability to move oral structures, such as the tongue and lip, independently of each other) (Kumin n.d.). Clinical experience suggests that the acquisition and maturation of oral-motor movements underlie sound production and feeding skills (e.g., sucking, biting, and chewing) (Arvedson and Brodsky 2002). Children with developmental disabilities may demonstrate oral-motor patterns that are not observed in typical development. Atypical oral-motor patterns include jaw thrusting, tongue thrust, tonic bite reflex, lip retraction, tongue retraction, and nasal regurgitation (Morris 1978). A child's oral-motor skills may be assessed by a speech-language pathologist.

Definition

Organizational skills are a set of techniques used by an individual to facilitate the efficiency of future-oriented learning, problem-solving, and task completion. Organization requires the integration of several elements to reach a planned goal. Dawson and Guare (2010) define organization as “the ability to design and maintain systems for keeping track of information or materials” (p. 1). The broader domain of executive functioning plays a large role in the development and execution of organizational skills. Executive functioning is the multifaceted construct used to describe higher order, goal-directed thinking involving planning, inhibition, flexibility, organized search, and working memory and is thought to be impaired in individuals with ASD (Gyori 2006). Organization can be considered a sub-component of the larger executive function construct.

Evidence suggests that individuals with autism spectrum disorders (ASD) have deficits in executive functioning abilities. For instance, impairments in flexibility, attention, and planning have been documented (O’Hearn et al. 2008). Those with ASD also have been noted to evidence dysfunction in their organizational skills (Kenworthy et al. 2005). This disorganization may be due to the presence of the aforementioned executive

functioning deficits and related regulatory sequelae, such as the fact that individuals with ASD have a greater tendency to overfocus on irrelevant details to the exclusion of conceptualizing the “big picture” (Kuschner et al. 2009). In contrast, people with ASD have been anecdotally noted to be highly organized regarding their special interests, such that they know every single detail about a topic and have organized the information quite well (Baron-Cohen 2009). To date, however, there is a relative dearth of research specifically focusing on the subcomponent of organization in individuals with ASD, their relationship to ASD symptoms and characteristics, their developmental unfolding, and their importance to developmental functions and outcomes. What literature is available has tended to address higher functioning individuals, with a focus on broader executive functions (e.g., Hill 2004). In this chapter, we provide an overview of the history of research on organizational skills within the context of executive functions in individuals with ASD; compare and contrast the development of organizational skills in typically developing children and children with ASD, along with potential etiological agents; and present emergent interventions that aim to improve organizational skills.

Historical Background

Organizational skills lie within the broader cognitive domain of executive functions. The empirical investigation of executive functions began in the 1980s, and research using samples of individuals with ASD soon followed, suggesting the presence of an array of difficulties as compared to typically developing individuals. In one of the first studies examining executive functioning in individuals with ASD, Rumsey (1985) used the Wisconsin Card Sorting Test (WCST) to compare the cognitive flexibility of adult men with high-functioning autism to the flexibility of a sample of age-matched typical adults. Rumsey found that individuals with autism demonstrated significant perseveration when compared to the control group, a finding that has since been replicated with

children and adolescents (Ozonoff et al. 2005; Prior and Hoffman 1990). Additional studies in the early 1990s revealed that individuals with high-functioning ASD had executive functioning deficits relative to other disorders, such as attention-deficit/hyperactivity disorder and learning difficulties, and across different cultures, suggesting that selected executive dysfunctions likely were core deficits in individuals with ASD (Ozonoff et al. 2005).

The study of executive functioning has evolved to better address the multidimensional nature of the construct, using a wider variety of outcome measures to consider other abilities such as categorization, working memory, inhibition, selective attention, and managing verbal feedback (Hughes 2001; Ozonoff et al. 2005). Indeed, a variety of models of executive function have now evolved (e.g., Stuss 2007; Friedman and Miyake 2017), and these are ripe for continued examination of their relevance for this population. Despite these advances, there remains a paucity of research specifically examining organizational skills in individuals with ASD.

The scientific examination of organization skills also is complicated by the tendency for individuals with ASD to be overly focused on details rather than conceptualizing the broad whole. Does this represent intact organization or, rather, disorganization due to the lack of attention to peripheral but important environmental details? One result of this tendency to overfocus on selected tasks is the difficulty with the generalization or the appreciation that skills learned in one context may be applied to other contexts (Volkmar and Wiesner 2009). Further, this approach to tasks may indirectly contribute to social skills difficulties, as to extract social information from various contexts requires both flexibility and the ability to organize this information in a meaningful way (Hughes 2001). Organizational skills also directly relate to an individual's success with academic and vocational demands, as well as activities of daily living, such as paying bills, grocery shopping, and keeping up with doctor's appointments. As such, the area of organizational skills is a critical one for clinical investigation and day-to-day functioning. For individuals with ASD,

organization and related executive functions have been associated with adaptive behavior (Pugliese et al. 2016), social functioning (Freeman et al. 2017), driving (Cox et al. 2016), and affective regulation (Wallace et al. 2016).

Current Knowledge

The Development of Executive Functions and Organization in Typically Developing Children

In a typically developing child, the development and application of organizational strategies begins in infancy. As children remember information, they store it in an orderly manner through the use of categorization (Berk 2002). Three- to five-month-olds have been found to categorize stimuli by shape, size, number, and other physical characteristics. Berk (2002) cited a number of studies providing evidence that infants not only organize their physical world through the use of categorization but their emotional and social worlds as well. This includes infants sorting people and voices by gender and age and the emerging ability to discriminate between emotional expressions. During early childhood (ages 2 through 6 years), children begin to use planning and sequencing in order to reach a goal with familiar or simple tasks. Children also begin to use strategies in problem-solving and move from less to more efficient strategies through practice, reasoning, and adult assistance, among other factors (Berk 2002). Generally, during these years, children will engage in a variety of executive functions, but they tend to be task or situation specific, with generalization of these skills being limited. By middle childhood (ages 6 through 11 years), children make more use of planning skills and begin to engage in generalizing these skills to other tasks and situations. For instance, they will decide how to order steps so as to accomplish a complex task and then utilize those strategies for another task or situation. In addition, children are able to utilize multiple strategies concurrently, and their long-term knowledge base becomes organized into more sophisticated, hierarchically structured networks (Berk 2002). Finally, adolescence to adulthood marks the development of more focused and

regulated attention, more effective and efficient strategy development and use, and an expansion of metacognition (Berk 2002). Taken together, these lead to more highly developed organizational capabilities and skills.

The Development of Executive Functions and Organization in Individuals with ASD

Although executive functions have been shown to be pervasively affected in many neurodevelopmental disorders across a range of ages and functional levels, less is known about the development of organizational skills in children with ASD or, more broadly, the developmental course of executive functions (O'Hearn et al. 2008). It has been theorized that although selected executive function deficits (i.e., set shifting and flexibility) have been demonstrated in young children with ASD (mean age = 5 years) relative to a control group of typically developing peers, these deficits are not autism-specific; but, instead, they are related to developmental delays. Another perspective with some empirical support is that executive functioning in preschool ASD is similar to that of young children with developmental delays matched on chronological and mental age, and suggests that executive dysfunction may emerge over the course of development and is not yet present (or observable) in early childhood. In that regard, these deficits are secondary in nature (Ozonoff et al. 2005). There is evidence that executive dysfunction and impairments may be most prominent during adolescence (Tsatsanis 2005; Rosenthal et al. 2013), particularly the application of planning and the goal-directed organization of information (Ozonoff et al. 2004). Kushner et al. (2009) discovered that while typically developing individuals demonstrated improvements in organizational and planning skills with age when reproducing the Rey-Osterrieth Complex Figure (ROCF), no similar qualitative differences in performance were displayed between children and adolescents/adults with HFA. In contrast, other findings have demonstrated improvements in executive function from childhood to adolescence in individuals with ASD, perhaps secondary to neuropsychological maturation; nevertheless, executive functioning

in adulthood was found to remain relatively impaired despite these developmental gains (Brady et al. 2017; O'Hearn et al. 2008). Longitudinal research is needed to better illuminate the developmental trajectory of the various dimensions of executive functions in children with ASD, with a specific need to include carefully considered covariates (e.g., nonverbal learning difficulties) (Hagberg et al. 2015).

Although much is to be learned regarding the development of executive functions, evidence related to planning and organization deficits has begun to surface over the past 10–15 years. Geurts et al. (2004) compared children with high-functioning ASD and attention-deficit/hyperactivity disorder (ADHD) on measures of executive functioning. These investigators reported that the errors made by the ASD group were related to difficulties with planning and cognitive flexibility, whereas errors by the ADHD group were better attributed to deficits in inhibition and fluency. Problems with planning efficiency and self-monitoring, which are closely related to organizational skills, have been documented in a number of studies (Tsatsanis 2005). Impaired performance on the Tower of London task was reported for children with ASD relative to typically developing controls, and was attributed to impaired planning skills and reduced strategy formation (Robinson et al. 2009).

Examining a sample of individuals with subthreshold autism traits, Christ et al. (2010) found a pattern of deficits in a number of executive functioning domains including planning, organizing, and setting goals as measured by the Behavior Rating Index of Executive Function (BRIEF). In contrast, Christ et al. (2010) did not find a relationship between autism symptomatology and the tendency to keep one's work space and materials orderly, as measured by the Organization of Materials Scale of the BRIEF. Overall, their work suggested that even individuals with subthreshold autism traits exhibit profiles of executive dysfunction, including deficits in organization/planning, similar to those of individuals with diagnoses of ASD. These findings suggest that executive dysfunction may appear on a continuum of

impairment, although it appears that problems with organizational skills of children with ASD may not be clearly dissociable from other childhood conditions (e.g., Tourette Syndrome, ADHD) (Hovik et al. 2017) – or even different subgroups of ASD (Blijd-Hoogewys et al. 2014). Adults with ASD who completed self-ratings of their broader executive functions did report their planning and organization skills to be mildly impaired, and significantly lower than typical controls (Davids et al. 2016).

Additionally, individuals with ASD have been noted to have difficulty copying and remembering the Rey-Osterrieth Complex Figure (ROCF), a task which requires visuospatial abilities, planning, and organization. Kenworthy et al. (2005) considered difficulty reproducing the ROCF, along with verbal organization deficits, to suggest impairments in organization. Kenworthy et al. (2005) expanded upon this suspicion to document deficits in the organization skills of individuals with high-functioning autism (HFA) and Asperger's disorder (AD) across several verbal and visual tasks. For example, although both high-functioning ASD groups were found to have intact ability to interpret discrete data, relative impairments were noted in their ability to integrate and organize complex information. Another discrepancy that the authors attributed to a deficit in organizational skills was the participants' ability to copy abstract visual information from a model but comparative difficulty with perceiving a visual gestalt when organizing puzzle pieces. Despite mean scores within the average range on several general cognitive measures, these investigators found relative impairments in a number of domains of executive functioning in the high-functioning ASD groups, including tasks specifically measuring organization [e.g., the Planning/Organization Scale of the BRIEF, the Story Memory subtest from the Wide Range Assessment of Memory and Learning (WRAML), and the Object Assembly subtest from the Wechsler Intelligence Scale for Children-III (WISC-III)]. In sum, while many previous studies have emphasized deficits in planning, a construct closely linked with organization, this study provided more direct evidence that

individuals with ASD have executive deficits in flexibility and organizational skills.

Despite these findings, however, the deficits do not appear to be directly linked to the core symptoms present in ASD, although recent theories have made an effort to assert this linkage (Baron-Cohen 2009). Further, from a clinical perspective, many clinicians will agree that their clients with ASD can be highly organized with respect to their restricted interests, perhaps being overorganized with respect to the intensity of their focus on these interests and their various components. For example, clinicians and researchers working with this population no doubt have been favorably impressed with the amount of focus, logic, and organization of information pertaining to a restricted interest. In many instances, these individuals actually have a knowledge base that would rival many experts in the targeted area, and their attention to the details pertaining to this information is exquisite. Anecdotally, this indicates that individuals with ASD are capable of goal-directed organization, although this skill is not always generalized and applied outside of their area of restricted interest and, for many individuals with ASD, herein lies the challenge.

Explaining Organizational Dysfunction

There are a number of possible underlying causes of, or contributors to, the impairments noted in organizational skills and other related aspects of executive functioning. Frith's theory of weak central coherence (Frith 1989) posits that individuals with ASD tend to process information in fragments rather than in terms of the coherent whole. Consequently, individuals with ASD may focus on minor, irrelevant details and fail to process the underlying meaning of the cohesive information (Hughes 2001). Without an understanding of the broader concept, it is challenging to effectively organize and process presented information. Mesibov et al. (2004) proposed that in addition to focusing on minute details, individuals with ASD are less capable of assessing and prioritizing their relative importance. For example, Mesibov et al. (2004) described a young man with ASD

who recalled having difficulty following a conversation that went from red balloons to birthday parties to the children enjoying themselves, because he became focused on "red balloons" and was unable to organize a schema for a birthday party. Although not stated directly, it is likely that this individual, or others like him, could tell you an enormous amount of information about (red) balloons in a detailed and organized fashion.

In addition, differences in executive functioning in individuals with ASD have been attributed to abnormalities in brain maturation (e.g., decreased synaptic pruning early in development, structural differences in regions of the brain such as the cerebellum, and decreased connectivity within the brain due to volumetric differences of white matter in the corpus callosum; Han and Chan 2017; Haznedar 2011; O'Hearn et al. 2008). For example, Just et al. (2007) found evidence of reduced intracortical connectivity resulting in a lower degree of integration of information across certain cortical areas. The investigators concluded the presence of deficits in the integration of information at the neural level which, in turn, contributed to cognitive impairments. While a fuller discussion of these neurobiological features of ASD is beyond the scope of this chapter, it is important to note that the neurological bases of executive dysfunctions in autism have yet to be fully explained (Han and Chan 2017; O'Hearn et al. 2008).

Interventions

Impairments in executive function skills, such as planning, prioritizing, and organizing, may become more apparent when children begin school. In this situation, they are required to keep track of their personal items, follow multi-step directions, engage in multistep assignments, and complete tasks in a set amount of time. Despite a need for structure and order, children with ASD may have messy desks and turn-in incomplete assignments (Moore 2002). In this regard, there does appear to be a significant need for specific interventions to improve selected types of organization skills. There is some notion

that various executive functions can be improved through intervention; however, there is a lack of strong empirical research looking at remediating executive functioning in children with ASD (Ozonoff et al. 2005).

One randomized controlled trial has emerged examining the utility of the Unstuck and On Target intervention versus social skills training to address executive dysfunction in children with high functioning ASD (Kenworthy et al. 2014). Forty-seven third to fifth grade students were assigned to the Unstuck and On Target intervention, and they were matched by age, gender, and race, IQ, ASD symptomatology, medication status, and parents' education to 20 students who were randomized to the social skills training. The interventions were implemented in 28 small group sessions (30–40 min in length) and were conducted in the school setting. Findings revealed significant improvements in organization and planning for the Unstuck and On Target group, with effect sizes being in the small to medium range. Improvements also were noted in problem solving and behavioral flexibility, with these findings translating into improved rule-following behaviors and significantly better capabilities to make transitions. Given the potentially pervasive nature of these problems, interventions may require collaboration between schools and families, organizational aids, and significant day-to-day structure (Volkmar and Wiesner 2009). Although there are some medical treatments that have shown promising early results (e.g., repetitive transcranial magnetic stimulation) (Ameis et al. 2017), educational and behavioral strategies currently remain the best options for improving organizational skills.

To date, from a best practice perspective, a number of strategies have been offered to address organizational problems. Volkmar and Wiesner (2009) recommended a stepwise approach, consistency and predictability, the use of functional routines, providing time to process/prepare, and the use of aids such as visuals, organizers, and computers. Moore (2002) suggested physically organizing the classroom and using color coding, visuals, daily schedules, checklists, teaching children to find the main idea rather than focusing on

irrelevant details, and using an assignment notebook, among other aids. Dawson and Guare (2010) proposed that children lacking intact organizational capacity should be provided with organizational schemes. The children should be cued to use the organizational scheme and receive reinforcement for using it. An example for organizing a backpack provided by Dawson and Guare (2010) is to use specific pockets and compartments, which can be labeled or color coded for lunch, permission slips, money, and homework. This latter example also may capitalize on the cognitive rigidity, or need for "sameness," typically evidenced by many individuals with ASD. More generally, this approach also suggests the need for a thorough evaluation of various executive functions, including organizational capabilities.

Many of the aforementioned suggestions to remedy the difficulties associated with executive dysfunction are related to concepts from structured teaching. Structured teaching, a cornerstone of the TEACCH (Treatment and Education of Autistic and Communication handicapped CHildren) program, is based on the premise that clear structure and organization make the environment more navigable for individuals with ASD by clarifying expectations and enabling communication. This is achieved through the use of physical organization, visual support, and schedules (Hartford and Marcus 2011). Goals of physical organization (e.g., dividers, clearly delineated areas for specific activities) include the addition of contextual clues, clarification of boundaries, and the minimization of distractions and stimulation. Visual supports are utilized to capitalize on the tendency for individuals with ASD to have relatively strong visual learning abilities and include picture prompts, video modeling, ordered pictures, or step-by-step written directions, which can help in attention and sequencing. Schedules can be used to establish functional routines and add predictability to the day, and they can indicate a sequence through words, pictures, or objects to facilitate smooth transitions and temporal understanding. In general, built-in organization through structured teaching methods can help individuals with autism effectively understand and participate in the world around them (Hartford and Marcus 2011).

Direct instruction interventions with empirical support, such as providing organizational skills training, can also be used to improve the skills of children with ASD in the classroom. For example, in one of the few evidence-based studies related to organization training in ASD, elementary-age children with high-functioning autism and Asperger's syndrome were found to increase the percentage of items correctly filed and decrease the number of seconds needed to retrieve a requested item following an intervention teaching the children self-monitoring skills and the use of a file box system to enhance organization (Dorminy et al. 2009).

Future Directions

This encyclopedia entry has addressed an important but targeted area of executive functioning in the ASD population; namely, organizational skills. Despite the range of studies that have been focused on executive functions in this population, few empirical studies have specifically examined the subcomponent of organization. The empirical literature that does exist in the domain of organization, and even executive functions more broadly, typically has studied individuals with high-functioning ASD, although it is noteworthy that more recent studies have begun to include individuals with ASD who have a broader range of overall functioning. It would be worthwhile for future research to not only examine profiles of executive functions that would include organization, but also to examine these profiles in lower functioning populations. While some might argue that these problems may not be high on the priority list of needs for many of these individuals, such research could shed light on how organizational deficits contribute to the presence of aggressive, self-injurious, and repetitive behaviors as well as to the overall adaptation of individuals with ASD who are higher functioning.

For instance, it has been theorized that individuals engage in repetitive behaviors when interpreting social situations as unpredictable as a means to impose order (Hughes 2001); thus, an

understanding of how individuals with ASD differentially order and organize both social and nonsocial information might provide additional strategies for implementing successful interventions. In addition, although there is a breadth of research on neurodevelopmental constructs such as attention, memory, language, and temporal-sequential ordering, there is limited research specifically investigating organization in individuals with ASD, the developmental course of organizational skills throughout the life span in this population, or how this cognitive function contributes to ASD symptom manifestation.

Finally, there remain a myriad of additional questions related to the organizational skills of individuals with ASD. In addition to examining the multidimensionality of these skills across all ages and levels of functioning, questions pertaining to their generalized versus specific nature, associated measurement strategies, their relationships to core and associated symptoms in ASD, and their linkages to evidence-based practices all remain unanswered at present. Specific studies addressing the organizational skills of individuals with ASD will continue to advance our knowledge of how these skills facilitate our overall understanding of ASD.

Orienting Response

Lauren Turner Brown

Department of Psychiatry, Carolina Institute for Developmental Disabilities, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Definition

Orienting as has been defined as the aligning of attention with a source of sensory input (Posner et al. 1998). Research in autism has focused on how individuals with autism orient to different types of stimuli (e.g., visual, auditory, social, non-social) in different contexts (e.g., computer paradigms, naturalistic settings). Further, the components to orienting, disengagement of attention and shifting attention, have been studied to evaluate possible deficits in both areas. Results have varied, however, depending upon the age of participants, comparison groups, and orienting paradigms. Considerable research has found that children with autism orient less frequently to social information than their peers and that their orienting to nonsocial stimuli is relatively less impaired (Dawson et al. 1998, 2004; Swettenham et al. 1998). Further, social-orienting impairments are more commonly observed in natural settings than when completing computerized tasks (Greene et al. 2011). Social-orienting impairments, often

recognized clinically when children do not respond to hearing their name called, are among the earliest observable symptoms of autism (e.g., Baranek 1999; Nadig et al. 2007). Research has demonstrated that children who orient more readily to social stimuli develop stronger joint attention and language skills over time (Dawson et al. 2004), supporting theories of the potential pivotal role social orienting may play in development of children with autism (Dawson and Lewy 1989; Mundy and Neal 2001).

Ornitz, Edward

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Name and Degrees

Edward M Ornitz

- 1945–1948 B.S. Stanford University, Palo Alto, California
- 1948–1952 M.D. Stanford University, School of Medicine, Palo Alto, California.

Major Appointments (Institution, Location, Dates)

- 1952–1953 Internship, Los Angeles County General Hospital, Los Angeles, California
- 1955–1958 Psychiatry Residence and Research Fellow, Yale University School of Medicine, New Haven, CT
- 1958–1960 Fellow in Child Psychiatry, Child Study Center, Yale University, New Haven, CT
- December 1960–February 1965 Staff Psychiatrist, Reiss-Davis Clinic for Child Guidance, Los Angeles, California.
- September 1963–July 2006 Clinical Instructor, Assistant, Associate, and Full Professor in Residence, Department of Psychiatry, UCLA School of Medicine.
- July 2006–Present Professor Emeritus, Department of Psychiatry, UCLA School of Medicine.

Major Honors and Awards

Dr. Ornitz has been invited to and delivered presentations at numerous national and international meetings. He has been the recipient of numerous grants.

Landmark Clinical, Scientific, and Professional Contributions

A pioneer in the study of psychophysiological methods in the developmental neuropsychiatric disorders, Dr. Ornitz's research has focused on brain mechanisms used to modulate arousal and stress. In addition to his long-standing interest in autism, he has conducted work in areas such as anxiety disorders, response to pain, posttraumatic stress disorder, and various medical conditions. His laboratory has developed many techniques now widely used in the field.

Short Biography

A pioneer in the study of neurobiological process in autism, Dr. Ornitz and his colleagues were among the first to question the widespread early views of psychogenetic models of autism. This work included earliest studies of a range of neurophysiological processes including responses to vestibular stimulation, sleep, and brain stem-evoked responses. He also worked to apply some of the measures he developed in study of anxiety and PTSD. The author of 129 scientific publications, Dr. Ornitz was an active teacher as well as a research and trained several generations of workers at UCLA.

Otitis Media

Jennifer McCullagh
Department of Communication Disorders,
Southern Connecticut State University, New
Haven, CT, USA

Synonyms

[Middle ear infection](#)

Definition

Otitis media is a middle ear infection that can cause a temporary hearing loss in the affected ear, or ears. The middle ear is a closed cavity in the temporal bone that is connected to the nasopharynx by the Eustachian tube. In early stages of otitis media (acute otitis media), the middle ear space becomes inflamed and pressure builds causing the tympanic membrane to stretch leading to intense pain. Acute otitis media can be treated with antibiotics, but most cases of otitis media resolve on their own within 2–4 weeks. When otitis media becomes chronic, fluid builds up in the middle ear space, but it is less likely to be painful.

Chronic otitis media is not typically responsive to antibiotic treatment but can be treated with tympanostomy tubes. Tympanostomy tubes can be placed in the tympanic membrane when the condition is either chronic, causing a hearing loss greater than 15 dB, influencing speech/language, or disrupting the learning process in school. Otitis media is reportedly more common in individuals with autism spectrum disorders than in the general population (Konstantareas and Homatidis 1987; Rosenhall et al. 1999; Smith et al. 1988), but more systematic research needs to be done to further investigate this relationship.

Outcome Studies

Patricia Howlin¹ and Philippa Moss²

¹Institute of Psychiatry, Psychology and Neuroscience, King's College, London, UK

²Psychology, Great Ormond Street Hospital, London, UK

Definition

Outcome studies describe the progress of individuals with autism as they move through adolescence and into adulthood. Some such studies have followed up groups of individuals first diagnosed as children over a number of years; others have involved investigations of different individuals at different ages. Follow-up studies of the same individuals from child to adulthood are particularly informative as they allow the investigation of factors in early childhood that may help to predict outcome in later years.

Historical Background

The earliest studies of outcome in autism were conducted in the 1950s by Leon Eisenberg (a colleague of Leo Kanner) in USA and Mildred Creak in England. Eisenberg, writing in the 1950s, documented the wide variety of possible outcomes. Many of the individuals he described

remained very dependent on others for support, but about one-third were found to have made at least a “moderate social adjustment,” despite the lack of any specialist provision or treatment available at that time. A minority had managed to achieve good independence, although even among this group social impairments remained apparent. In a slightly later report from Britain, Mildred Creak described 100 cases of “childhood psychosis,” the term then often used for children with autism. A minority was rated as having made significant improvements, but around half were permanently institutionalized. Some years later, Kanner followed up 96 young adults whom he had first diagnosed as children. Just over 10% were described as achieving relatively highly as adults and “mingling, working, and maintaining themselves in society.” Kanner (1973) noted that in the majority of these cases, “a remarkable change took place” around their mid-teens. “Unlike most other autistic children they became uneasily aware of their peculiarities and began to make a conscious effort to do something about them.” In particular, they tried to improve their interactions with their peers, often using their obsessional preoccupations or special skills “to open a door for contact.” Asperger (1944) also reported positive outcomes for some of the individuals he had initially described, including a professor of astronomy, mathematicians, technologists, chemists, high-ranking civil servants, and an expert in heraldry. Again, it was often individuals’ special skills or interests that facilitated social integration. However, like Eisenberg, both Asperger (1944) and Kanner (1971) highlighted the wide heterogeneity in outcome among individuals with autism, and how trajectories of development could change markedly over the years “ranging all the way from complete deterioration to a combination of occupational adequacy with limited, though superficially smooth social adjustment” (Kanner 1971).

Over the course of the last 60–70 years, many subsequent studies have been conducted exploring the prognosis for individuals with autism as they move into adulthood, and the factors affecting outcome.

Current Knowledge

In recent years, there has been a steady increase in the number of studies that have followed up individuals with autism from childhood into early adulthood and beyond. In order to facilitate comparisons between studies, many such studies have adopted a somewhat simplified categorization system, classifying participant outcomes as “very good” if they were employed, had friends, and high levels of independence; “good” if they were working with support, had some friends, and could travel independently; “fair” if they required support in daily living but had some autonomy; “poor” if they had very limited autonomy; and “very poor” if they were living in highly specialized or very restrictive environments. Magiati et al. (2014) conducted a systematic review of follow-up studies published between 1967 and 2013 (25 studies; n participants = 2043; age range 17–44 years). Although the average IQ of most of the cohorts involved was relatively high (mean = 79.0), almost 50% of participants were rated as having “poor” or “very poor” outcomes. Most remained highly dependent on others for their care and few had developed close friendships or intimate relationships. Average employment rates were 30%, and among those in employment, jobs were mainly low-skilled, part time, and very poorly paid. Indeed, adults with autism tended to be more economically, educationally, and socially disadvantaged than other groups of individuals with developmental or intellectual disabilities (Roux et al. 2013). A subsequent review by Steinhausen et al. (2016) reported similar, rather depressing findings. Thus, of the 12 studies included in that review (dates 1967 to 2014; n = 828 individuals), 48% of participants were rated as having a “poor”/“very poor” outcome, and only in 20% was outcome classified as “Good.” Outcomes for some recent cohorts of individuals with higher levels of ability are somewhat more positive (e.g., Gotham et al. (2015), Helles et al. (2017), Roy et al. (2015), and Taylor et al. (2015). See Howlin and Magiati 2017 for review), but even among these groups, social attainments are much lower than in the general population.

In their review, Steinhausen et al. (2016) also highlight the wide variation across studies. Thus, the mean estimated percentage of individuals reported to have a “good outcome” was 20% but with 95% confidence intervals varying from 14% to 27%; confidence intervals for the proportion with a “poor outcome” ranged from 37% to 59%. Many of these differences are due to the heterogeneity of the cohorts involved, with respect to age, IQ and language, autism severity, and many other factors. Different outcome measures also add to the complexity of comparing across studies, or over time. In particular, there is growing dissatisfaction with traditional “objective” measures of outcome that focus primarily on employment, jobs, independent living, and close relationships. More recently, therefore, there has been a move toward more subjective outcome measures that may be more appropriate for individuals with autism. These include factors such as satisfaction with life, good physical and mental health, adequate living conditions, and supportive and positive social and family relationships. When these variables are taken into account, adult outcomes can appear much more positive than usually reported (Bishop-Fitzpatrick et al. 2016; Hong et al. 2016; Helles et al. 2017).

Although “normative” measures of social outcome generally indicate that, as a group, adults with autism are much more socially, economically, and educationally disadvantaged than their peers, follow-up studies have also been important in highlighting the very positive changes that can occur at an individual level. Thus, typically, there are improvements in verbal and nonverbal communication and in social interactions, while ritualistic, stereotyped, and “maladaptive” behaviors tend to decrease from child- to adulthood (Lord et al. 2015; Woodman et al. 2015; see Howlin and Magiati 2017 for review). However, it is also evident that individual trajectories can be very variable, and it remains very difficult accurately to predict adult outcomes from early child characteristics. Lord et al. (2015) have described a number of different trajectories of development in cognitive, verbal, and social skills, and in repetitive behaviors, and they highlight the importance of further work in this area, both for identifying the specific genetic etiologies

underlying different phenotypes, and for developing more individually tailored interventions.

Future Directions

It is evident that, in the 70 years since autism was first formally described by Kanner, there have been significant improvements in outcome. In cohorts studied before 1980, almost no individuals had received full-time education, very few lived independently or had jobs, and over half of all adults were placed in long-stay hospitals or institutions for people with mental retardation (Howlin 2014). For example, in the very early studies of Rutter and colleagues (Lockyer and Rutter 1969, 1970; Rutter et al. 1967), most children had never attended full-time school and many spent their adult years in institutions. Over the last few decades, access to early diagnosis, more intensive intervention programs, specialist educational support, in both school and college, and supported employment programs have greatly increased. There have also been increases in the numbers of individuals living in their own homes, either independently or with some minimal supervision, and of the numbers of individuals in employment (see Howlin and Moss 2012). Nevertheless, the overall findings from current follow-up research indicate a poor prognosis for most individuals with autism, at least when standard measures of “good” social outcome are employed. Relatively few individuals, even those of high IQ, achieve full independence and social integration in adult life. The financial costs of supporting adults with autism also remain very high, due to their continuing need for medical care, residential or supported living accommodation, and to productivity loss, both by caregivers as well as by individuals themselves (Leigh and Du 2015). Furthermore, despite the huge expansion in intervention research for children with autism over recent years, there is, so far, little evidence that early intervention programs have had any significant impact on improving life-time prospects. In the field of autism, adult intervention research lags far behind child intervention research in both quantity and quality (NICE 2012). A lack

of appropriate services for adults, especially those of average IQ, also means that they remain very disadvantaged compared with the general population and indeed with adults with other forms of disability (Roux et al. 2013). There is also a significant gap in knowledge about what happens to individuals with autism as they approach old age (Wright et al. 2016). Almost all current adult outcome studies have focused on younger individuals in their 20s to 40s. There is little research on individuals in the middle years and no large-scale studies of outcome in those aged over 60. To date, knowledge about the aging process in autism is extremely limited and systematic information about the physical and mental health needs of elderly people with autism is lacking. For example, it is not known whether rates of dementia are likely to be higher or lower in this group than in the population as a whole. It is also evident that many individuals remain highly dependent on their families for support throughout adulthood. How they will cope when parents are no longer able to support them is a further issue with major implications for society as a whole.

Overcorrection

David McAdam¹ and Vicki Madaus Knapp²

¹Department of Pediatrics, University of Rochester Medical Center, Rochester, NY, USA

²Applied Behavior Analysis (ABA) Program, Daemen College, Amherst, NY, USA

Definition

Overcorrection is a behavioral intervention developed by applied behavior analysts and is based on

the belief that the challenging behavior of persons with autism spectrum disorders are maintained by social factors (e.g., attention from other people, escape or avoidance from low-preference academic activities such as math) or nonsocial factors (e.g., sensory reinforcement). Overcorrection is a name given to a package of procedures that consists of two components (restitution and/or positive practice). Restitution consists of requiring the person displaying challenging behavior to correct their actions to a state that is vastly improved from what existed prior the occurrence of the challenging behavior, sometimes repeatedly. For example, if a child throws a toy truck at his or her teacher, they might be required to pick up the truck and then clean up the play area of their classroom. Positive practice consists of having an individual engage an adaptive behavior that is functionally incompatible with their challenging behavior (e.g., playing with the truck appropriately and then putting it away in the correct location), sometimes repeatedly. Depending on the problem behavior targeted, restitution and positive practice may be used either in combination or alone.

Historical Background

Overcorrection is an applied behavior analytic intervention developed by Richard Foxx and Nathan Azrin in the early 1970s. In their early studies, Foxx and Azrin demonstrated that overcorrection could successfully reduce a wide range of challenging behavior including (a) aggression toward other people, (b) biting of fingernails, (c) inappropriate mealtime behavior (e.g., tossing food on the floor), (d) pica (e.g., eating nonedible objects), (e) stereotypic or other interfering repetitive behavior, (f) self-injury, and (g) toileting accidents of individuals with autism and other developmental disabilities (Foxx and Bechtel 1983). For example, in 1974, Azrin and Wesolowski showed that overcorrection could be used to reduce the food stealing of 34 persons with autism or other intellectual disabilities living in an institution. If a person took food from another person, they were required to return the food (restitution) and to buy more food and give

it to the person from whom they had stolen (positive practice). Since the publication of Foxx and Azrin's initial studies, multiple independent researchers have successfully replicated the findings of their studies providing data-based evidence that overcorrection is an evidence-based intervention. **That is, overcorrection meets the standards for independent replication established by panels of experts.**

Rationale or Underlying Theory

In the behavior analytic literature, overcorrection is classified as a punishment-based strategy (Foxx 1982; Foxx and Bechtel 1983). If overcorrection is used contingent on the occurrence of a targeted challenging behavior and the frequency of the behavior decreases in the future, then the behavioral definition of punishment is met (see Azrin and Holz 1966 for a technical behavior analytic definition of punishment). According to Foxx and Bechtel (1983), overcorrection also often works due to negative reinforcement. That is, individuals often engage in behaviors designed to avoid or terminate its use. In their early publications, Foxx and Azrin provided two rationales for the use of overcorrection. First, overcorrection was described as promoting "normalization" by employing consequences which typically developing people apply to themselves when they display challenging behavior which is judged to be socially inappropriate. For example, someone who is angry and throws paper on the floor would pick it up. Second, overcorrection, unlike most other behavioral reductive procedures (e.g., time-out, response cost), provides the clinician with the advantage of being able to provide an educative consequence which is functionally equivalent to an individual's challenging behavior. Thus, overcorrection may be beneficial to an individual by helping them experience the effort required by other people to correct the damage caused by their challenging behavior. Some researchers also have argued that when overcorrection includes a positive practice component, it is less restrictive than other punishment-based strategies (e.g., time-out; contingent exercise)

because it also teaches adaptive functionally equivalent behavior. Although overcorrection has typically been implemented contingent on the occurrence of challenging behavior, the authors of a small number of studies have implemented it based on the absence of a behavior. For example, Foxx (1977) used overcorrection to increase the eye contact of children with autism and intellectual disabilities (e.g., contingent on the lack of eye contact, a child was required to practice looking at the face of another person).

Goals and Objectives

Overcorrection is an intervention designed to reduce the challenging behavior of persons with autism (e.g., aggression, property destruction, self-injury, and pica).

Treatment Participants

Individuals who are dually diagnosed with an autism spectrum disorder and a moderate to profound intellectual disability are most likely to benefit from overcorrection. Prior to the participation in the clinical use of overcorrection, a comprehensive functional behavioral assessment should be conducted and less restrictive; potentially effective interventions should be attempted (e.g., functional communication training, differential reinforcement of other behavior). Given the restrictiveness of the intervention, evaluation of overcorrection using a single-case experimental design that rules out threats to internal validity and the conducting of frequent fidelity checks is recommended.

Treatment Procedures

The published literature contains a variety of procedural variations of overcorrection. Both the topography of the overcorrection responses and duration of the application have differed widely from study to study. Gross motor movements with

physical guidance termed “functional movements training” by Foxx and Azrin (1973) are the most commonly used positive practice procedure reported in the literature. This procedure involves instructing a person to hold a body part in a particular position for predetermined length of time while providing physical guidance to ensure that the person engages in the correct topographical form for the required number of repetitions. Contingent on stereotypic hand clapping, Foxx and Azrin (1973), for example, required a 7-year-old boy with autism to engage in 5 min of functional movement training. The boy was required to engage in a series of hand placements each for approximately 15 s (e.g., hands above head, hands straight out in front of him, hands in pockets). While the majority of studies have used gross motor movements which are topographically similar to the target behavior, a few studies have employed arbitrary movements suggesting that the contingent relationship between the targeted behavior and motor movements is more important than the similarity of the topography. For problem behavior involving physical aggression toward other people or property destruction, positive practice typically involves requiring a person to be quiet and relaxed for a prespecified period of time (e.g., laying calmly on a mat for 15 min before practicing picking up and putting away toys). For inappropriate mouthing or ingesting of objects, positive practice usually involves cleaning a person’s mouth and lips with mouthwash contingent on the targeted behavior. In the published literature, researchers have examined the use of varying durations of overcorrection (e.g., 10 s, 15 min). However, the lack of parametric studies comparing the use of varying durations of overcorrection makes it difficult to identify the most appropriate duration to recommend to clinicians.

Efficacy Information

A variety of strengths and limitations of overcorrection have been identified in the published literature. First, several studies have demonstrated that overcorrection has produced a clinically significant reduction in behavior after other behavioral

interventions had failed (e.g., differential reinforcement of other behavior, verbal reprimands, time-out, simple correction). Second, published research studies using single-case experimental methods have shown that often overcorrection produces a rapid reduction in challenging behavior for many participants. Therefore, overcorrection may be a useful intervention strategy for persons whose challenging behavior routinely results in injury to self or other people (e.g., bruising) or is potentially life threatening (e.g., pica). Researchers have also suggested that the educative aspects of positive practice shift the attention of parent and teacher from focusing on the suppression of problem behavior to the adaptive skills that need to be taught to replace the challenging behavior.

Several potential limitations of overcorrection also have been identified. First, overcorrection requires the person participating in the intervention to engage in the corrective and alternative behaviors immediately following the occurrence of challenging behavior. Although many people immediately respond to verbal instructions to engage in the corrective and alternative behaviors, some people require physical prompts to do so. A person may resist attempts to physically prompt them, and in some cases, they may become aggressive or require a fair amount of physical effort to guide them through the intervention. Alternative interventions should be used with individuals who are too aggressive or resistant to potentially experience injuries. Another potential limitation is the high level of supervision and time required to implement overcorrection. In order to implement overcorrection correctly, the person implementing it needs to be continuously available and in close-enough physical proximity to implement the intervention and to consistently use physical prompting, when necessary.

Since the publication of Foxx and Azrin’s early research, there has been much debate about the use of punishment-based intervention strategies. This debate has centered around two positions. From a right-to-effective treatment perspective, some people have argued that persons with autism and other developmental disabilities have the right to the most effective treatment and for some individuals, this might support the use of a potentially quick-acting punishment-based

intervention. Other people argue that advancements in intervention strategies such as functional communication have eliminated the need for the use of punishment-based intervention strategies. The controversy concerning the pros and cons related to the use of punishment-based interventions warrants careful consideration by parents, teachers, and clinicians prior to the implementation of overcorrection.

The majority of research studies evaluating overcorrection have used single-case research designs and methods and have demonstrated that overcorrection generally produced a clinically significant change in behavior. The overcorrection literature could potentially benefit from the conducting of clinical trials, the manualization of intervention procedures, and the conducting of quantitative meta-analytic reviews.

Outcome Measures

Direct observational measures such as frequency or rate of occurrence of the targeted behavior or percentage of observational intervals in which the target problem behavior occurs are the outcome measures used to evaluate whether overcorrection produces a clinically significant reduction.

Qualifications of Treatment Providers

Minimal qualifications for the implementation of overcorrection include a master's degree or doctoral degree in applied behavior analysis or psychology with specific training in functional behavioral assessment and applied behavior analytic interventions for challenging behavior.

Definition

The social and cognitive deficits in autistic spectrum disorder (ASD) patients remain a therapeutic

challenge for both health care professionals and family (Cataldo et al. 2018). In recent years, several clinical studies showed the neuropeptide oxytocin, which facilitates trust, bonding, and communication, is decreased in ASD patients and other neuropsychiatric disorders (Cataldo et al. 2018; Peñagarikano et al. 2015; Vanya et al. 2017; Zhang et al. 2017). Specifically, several clinical studies demonstrated that administration of oxytocin improved social and cognitive skills in animal models and ASD patients (Cai et al. 2018; Cataldo et al. 2018; Peñagarikano et al. 2015; Vanya et al. 2017). Furthermore, these studies indicate that oxytocin improves social-cognitive function through three G-protein coupled receptors: OXTr, AVPR1a, and AVPr1b (Cataldo et al. 2018). Further clinical trials are needed to assess the efficacy and diagnostic potential of oxytocin in the treatment and prognosis of ASD.

Pain in Autism Spectrum Disorders

David Moore¹ and Michelle D. Failla²

¹School of Psychology, Liverpool John Moores University, Liverpool, UK

²Department of Psychiatry and Behavioral Science, Vanderbilt University Medical School, Nashville, TN, USA

injury/tissue damage), it is often possible to see the noxious input, although this is not always the case. This potential noxious input is then communicated along peripheral fibers before reaching the spine, at which time it can be modulated either up or down. Subsequently, in the brain, neural responses to this noxious input are then contextualized with associated suffering to generate a pain percept.

Definition: Pain

Pain refers to “an unpleasant sensory and emotional experience associated with actual or potential tissue damage.” It is important therefore to understand that pain is more than a simple “ouch” and refers to the emotional, cognitive, and social aspects associated with potentially noxious physical sensations. Therefore, the current entry will focus on responses to tactile, thermal, and chemical stimuli which have the potential to result in unpleasant sensations. This entry will not consider distressing responses to emotional or other sensory experiences; for a review of these, see the entry ► [“Sensory Processing”](#).

To understand both the experience of pain, the expression of pain, and the relationship of these to ASD, it is also important to consider the process by which pain is perceived and then communicated. When considering painful events that start in the periphery (e.g., pain resulting from an

Pain in ASD: Context

In addition to the social-communicative and repetitive behavioral routines which are characteristic of autism, there is a growing recognition that a significant percentage of those who have an autism diagnosis also show evidence of altered sensory responses (for more comprehensive reviews, see ► [“Sensory Features as a Marker of Autism Spectrum Disorders”](#), ► [“Short Sensory Profile in Autism”](#), ► [“Sensory Impairment in Autism”](#), ► [“Sensory Processing”](#), and others). Within the *Diagnostic and Statistical Manual* 5th edition, a specific example of sensory atypicality was given as an “insensitivity to cold/heat/pain.” Thus, a greater understanding of pain responsiveness in ASD is warranted.

Pain response in ASD is an important issue, as pain may be the first or only sign of illness or injury. Importantly, individuals with ASD are both at greater risk of injury and having other medical complaints that require potentially

painful medical procedures; thus, altered pain responsivity could be highly problematic. Concern about a proper understanding of pain in ASD is compounded by the communicative and intellectual challenges present in a significant proportion of individuals with ASD, which may mean many are less able to accurately report the degree and nature of pain experience. Further, self-injurious behaviors and co-occurring pain-related medical conditions, such as chronic gastrointestinal distress, are common in ASD and could reflect altered pain perception. Successful pain management is crucial: pain hyposensitivity can result in inadvertent injury and reduced treatment, while hypersensitivity to innocuous sensory stimuli can result in pain-like behaviors or anxiety. Without a clear understanding of how pain is experienced and communicated in ASD, there is a greater risk for mismanaged pain in ASD.

The aim of the current entry is to discuss the evidence for an altered pain experience in ASD. This entry is organized into a number of subsections: Case Studies, Self-Reported Pain Experiences and Responses, Observational Evidence, Laboratory Psychophysical Studies, and Neuropsychological and Neuroimaging, followed by a Summary with Future Directions for Research.

Case Studies

The earliest accounts of pain alterations in ASD come from a number of either clinical or anecdotal observations of people with ASD who did not display typical signs of pain or distress in response to experiences which most people find painful. Early anecdotal accounts include a child putting a car cigarette lighter into their mouth without crying out or a child who did not respond “even when struck hard.”

Further clinical accounts have more formally reported altered pain behaviors. The most widely discussed case is of a girl, “Sally,” who would play in the snow without clothes on (Wing 1976). Other accounts include a boy who placed his hand on a stove and was only alerted to the burning sensation by the smell.

These cases are often more complex: in two cases adolescents with ASD were reported to respond atypically to injuries (i.e., not responding when holding the hot handle of a frying pan); however, the same individuals reported having frequent headaches and chronic abdominal pain. See below in this entry for more information about chronic pain in ASD (Bursch et al. 2004).

Estimates of the number of individuals with ASD who might have reduced pain sensitivity have suggested that for those in inpatient care, this may be between 25% and 55% who have an observable reduction in pain (Gillberg et al. 1985). These populations were however generally nonverbal, and the modes of determining reductions in pain responses are unclear.

Self-/Parent Report

Self-report of pain is considered the “gold standard” of pain assessment. As such, most studies in ASD populations have compared self-report and caregiver reports of pain to the general population. These measures rely on memories for pain, which may be unreliable, as well as the ability to make judgements of others’ private pain state. Similarly, self-report requires internal assessment of one’s own pain to then make a comparison. This may present particular challenges given the evidence of difficulties with interoception in ASD (see the entry ► “[Interoception](#)” for more information).

Self-reported studies of pain response in ASD provide contrary evidence with some studies suggesting that individuals (8–54 years old) with ASD reported lower pain thresholds compared to IQ-matched typical controls on the sensory sensitivity questionnaire (Minshew and Hobson 2008). However, scores in the Charleston Pediatric Pain Pictures and a Faces Pain Rating Scale suggest no difference with adolescents with ASD- and IQ-matched controls (Bandstra et al. 2012).

Others have taken the alternative approach by asking parents to report on the pain that their children experience. Approximately 40% of parents have reported that their child shows either reduced or greatly reduced pain sensitivity. There are challenges using this approach as this still

involves the ability to compare one person's private experience to another. Parents must also make assumptions about their child's internal state, which assumes a shared socially communicative representation.

It is also important to consider how those with ASD discuss their pain with others. It has been suggested that children with ASD can use body diagrams to indicate the location of pain; however, they may struggle in using intensity scales for pain (neurotypical children often also find these difficult). Although there are vast differences regarding the language that children may be able to use to discuss pain (some using words like "excruciating" or "twisting"), they most generally prefer to discuss "hurt" rather than "pain." It was also notable that children generally preferred not to spend time discussing their pain. Children with ASD may also prefer to use parents or carers as a "gatekeeper" to discuss their pain. Thus, studies are needed to incorporate differences in pain communication across the lifespan for people with ASD.

Observational Studies

A major approach to understanding the pain responses of people with ASD, and in particular those who are either unable to communicate verbally or have limited verbal communication, has been to observe behaviors in the context of potentially painful medical procedures. These have been conducted with both recognized/standardized schedules and more general measures. These studies still tend to measure only socially communicative displays of "pain," yet they benefit from an impartial observer and discrete episode of standardized pain.

Studies have generally focused on observations of venepuncture procedures; however, the measures of pain taken during these procedures have varied. Studies have shown that children with ASD show greater facial activity (Childhood Facial Action Coding System) during the needle insertion phase of the procedure, as well as extended facial and behavioral reactions following the procedure. Others have found

reduced behavioral reactivity, however elevated heart rate and plasma β -endorphin levels and increased self-injurious behaviors following the procedure.

These data reporting increased reactivity to pain are in contrast to hyporeactive diagnostic criteria and self-, parent, and clinician reports in individuals with ASD. Yet these studies cannot separate specific pain behaviors from a distress reaction due to an unfamiliar environment, with unfamiliar people and experiencing an unfamiliar sensation.

A further challenge of this approach and these studies is that independent of ASD, individuals with intellectual delay might have reduced social communication of emotions and in particular pain (Gilbert-MacLeod et al. 2000). Given that the populations in these studies were unable to report on their experiences during the procedure, it is unclear what the precise cause of their behaviors might have been.

Psychophysics

A wide range of psychophysical approaches have been used to quantify the response of individuals with ASD to potentially painful stimuli. Most studies have been broadly based on the German Neuropathic Pain Network (DFNS). These studies investigate the graded psychophysical response to stimuli, allowing quantification of clinically relevant perception and pain thresholds. Standardized protocols are essential in order to minimize variability and produce reliable and comparable results, as well as clinical feasibility in its application.

Early studies exploring this question generally focused on single modalities for pain assessment. These showed no differences between ASD adults and controls for electrocutaneous pain; however, ASD adults were more sensitive to pressure pain. Further, there have been conflicting findings about thermal pain thresholds with studies showing either no difference or greater sensitivity in ASD. More recently, two studies have utilized comprehensive psychophysical batteries. In each case, no clear evidence was found for altered pain perception in ASD (Vaughan et al. In press).

Neuropsychological Evidence

Examining neural responses to pain in autism provides evidence of altered neural processing of pain and a communication-independent assessment of pain responses. The *neural pain signature* (NPS, somatosensory regions, insula, anterior cingulate) (Wager et al. 2013) reliably responds in a linear fashion to perceived intensity of a pain stimulus. However, in adults with ASD, NPS responses are initially intact but dramatically decrease *prior* to the end of the painful stimulus, even while participants continue to report pain (Failla et al. 2018). In other studies, there is evidence that people with ASD have heightened neural responses during pain anticipation (Gu et al. 2018).

Neural responses to viewing pain in others (vicarious pain) overlap heavily with the NPS and may provide insight into pain processing and differences in communication about pain evident in autism. Vicarious pain is also important for understanding social learning about pain expression norms. Results from neuroimaging studies of vicarious pain in autism are mixed, with evidence of intact (Hadjikhani et al. 2014) and decreased neural responses (Krach et al. 2015).

Chronic Pain

Although research on co-occurring conditions in autism has received substantial interest in recent years (see the entry ► “Comorbidity” for review), comparatively little of this work has specifically explored co-occurrence with pain conditions and experiences. A recent service review has suggested that although autism has a population prevalence of approximately 1%, as much as 13.7% of patients in a pediatric chronic pain service might meet criteria for autism. Therefore, children and adolescents with ASD may be more susceptible to developing chronic pain complaints than their neurotypical peers (Lipsker et al. 2018). Interestingly, this increase in chronic pain presentation in ASD may be particularly prevalent in females with ASD; however, more data is needed to confirm these effects.

Importantly, individuals with ASD also experience a number of co-occurring conditions that

are inherently painful or could negatively impact pain (i.e., mood disorders (Failla et al. 2019) or sleep disorders (Richdale and Schreck 2009). In particular, gastrointestinal distress is commonly observed in children with ASD; estimates have suggested that approximately 25% of children with ASD may experience significant and persistent gastrointestinal distress at any time, and about half of these report abdominal pain as an important feature of this experience.

Potential Evidence from Animal Models

Studies in animal models suggest potential biological alterations in pain responsivity related to specific genetic vulnerabilities in ASD. Mouse models of ASD exhibit altered pain behaviors and/or neurobiology (i.e., *SHANK3*; Han et al. 2016), parvalbumin knockout (Wöhr et al. 2015). In this context, it is unclear if aberrant pain behaviors represent downstream consequences of primary sensory processing differences specific to ASD or nociceptive-specific functional differences. Interestingly, mice lacking pain-related genes (i.e., mu-opioid receptor) also exhibit ASD-like behaviors (Becker et al. 2014). Future work is needed to understand this complex overlap in ASD and pain biology.

Future Considerations

At this stage, it is important to appreciate the heterogeneity in this population. There is considerable need for a larger, more comprehensive study of pain behaviors and consequences in people with autism. It is also important to note that the laboratory approaches used above are based on a rather artificial context in which to experience pain. These studies rely on participants actively attending to a pain stimulus within a sterile medical or laboratory context with no clear motivational, emotional, social, or cognitive state. This is not how people typically experience pain in their environment where pain might be competing for attention with daily tasks/interests and associated with emotional states and concerns over health and recovery. It is therefore important that we

consider issues surrounding pain in daily context and how this might be experienced.

Understanding of the role of other psychiatric or emotional contributions to pain in ASD is needed. Presently, research has established that the magnitude of pain reactivity in ASD during injection and dental procedures is predicted by depression and anxiety (Garcia-Villamizar et al. 2019). This effect mirrors work in neurotypical populations and suggests that people with greater anxiety and depression experience greater pain and also suggests that factors related to pain in ASD may be similar to the general population. The role of anxiety in pain experience in ASD is an important issue, as anxiety has been shown to be highly prevalent in ASD (see the entries ► “Anxiety”, ► “Anxiety Disorders”, and ► “Generalized Anxiety Disorder” for more information about anxiety).

Further data also suggests that reduced thermal pain sensitivity may relate to IQ, suggesting that those with lower IQ scores also report higher pain thresholds (Duerden et al. 2014). It is however important to note here that the methods used to determine pain thresholds in this study are based on a reaction time-sensitive measure, and therefore slower motor or general processing speed may also result in greater reported thresholds (Williams et al. 2019). Intriguingly, these are also suggestions that greater reductions in pain behavior may be associated with more severe ASD symptoms.

One of the most frequently discussed issues related to pain processing in ASD is that of self-injurious behaviors (for more information about self-injurious behaviors, see the entry ► “Self-Injurious Behavior (SIB)”). A prevalent early opinion was that self-injurious behaviors were a sign of reduced pain sensitivity. Opinions have however changed in recent years, with observations that individuals with ASD may engage in self-injurious behaviors following potentially painful episodes suggesting that this might be a coping mechanisms to deal with pain. The role of self-injurious behaviors in pain experience and expression is however still unclear in ASD.

Understanding pain perception, experience, and expression in ASD is of critical importance. The presence of pain-related comorbidities, uncertainty regarding pain responsivity, and

communication difficulties that limit the reliability of standard pain assessments **makes the problem of pain management in ASD difficult and urgent**. Additionally, there are reported case studies showing that traditional analgesic approaches may not be as effective in some patients with ASD and that prescribing practices may differ in ASD. Yet, there are many other non-pharmacological options for pain management in neurotypical populations. Future work is needed to identify best pain assessment and management strategies in ASD.

Introduction

Pakistan is situated in South Asia, and with a population of about 210 million, it is the sixth most populous country in the world. Almost

35% of this population is under the age of 14 years. As is true for other Asian countries, the child and adolescent psychiatry services in Pakistan, including the services for autism and other developmental disabilities, are significantly lagging in comparison to its Western peers. There are few general psychiatry departments in major cities of Karachi, Lahore, Rawalpindi, Islamabad, Faisalabad, Multan, Peshawar, and Quetta; however, because of limited resources, their outreach services to rural areas are almost nonexistent, and it is in rural areas where nearly two-thirds of the country's population resides. The situation of divisions of child and adolescent psychiatry is bleaker as there are only a handful of child psychiatrists and very few training sites in the country. At present, there is only one inpatient child and adolescent psychiatry unit in Pakistan, which was established in 2012 at King Edward Medical University/Mayo Hospital in Lahore (Imran and Azeem 2014).

Current Status

Autism spectrum disorder is an evolving concept (Nazeer et al. 2019), and the current prevalence of autism spectrum disorder (ASD) in Pakistan is unknown. Because of the lack of integrated services, various health professionals, including child psychiatrists, general psychiatrists, neurologists, psychologists, pediatricians, and speech and language therapists, find themselves to be the first-line providers for this population and to make the diagnosis of autism. Because of the lack of any formal training for the above wide array of health care providers, no standardized screening tools for ASD are used in most practices. Along with these professionals, there are also strong cultural beliefs in getting treatment from traditional healers, who also sees a bulk of children with autism and other developmental disabilities. Current literature has reveals a low level of awareness and knowledge of ASD among healthcare workers and school teachers (Imran et al. 2011; Rahbar et al. 2011; Farooq et al. 2018). Various misbeliefs and misconceptions were found in these surveys regarding causes, diagnosis, and treatment interventions for autism.

In the above landscape, there are few glimmers of light as there are very few schools that are promoting the cause of adequate mental health for children and are providing specialized programs for this population. One of the earliest established schools in this regard is "Amin Maktab School" in Lahore, the second-largest city of Pakistan. Amin Maktab School was established in 1962, and by 1991, this institution was successful in building outreach programs for underserved areas of Lahore.

With the increased use of social media, increased literacy rate, and parental advocacy, different institutions are taking a more proactive role in serving this population. Children's Hospital, Lahore is one such example, which, as a tertiary care pediatric hospital, has developed a well-established program for autism and provides diagnostic and therapeutic services. Dow University in Karachi has also started an autism program in 2013. Sindh Provincial Government has also taken the lead in establishing the Center for Autism Rehabilitation and Training-Sindh (C-ARTS) in 2018. This center provides a wide array of comprehensive services for children with autism spectrum disorder in the largest city of Pakistan.

There are limited subspecialty training programs in the country, and at present, only one private teaching institute, Agha Khan University, Karachi, Sindh, is providing subspecialty training in child and adolescent (CAP) psychiatry in the country. To further the status of subspecialty training in this field, the College of Physicians and Surgeons Pakistan (CPSP) has recently approved a CAP fellowship of their own, which is based on the United States model of 2 years subspecialty training after finishing postgraduation in general psychiatry. Various individuals have played a key part in developing this fellowship from Pakistan, United Kingdom, and the USA including Prof. Mowadat Rana, Prof. Fareed Minhas, Dr. Nazish Imran, Dr. Ayesha Mian, Dr. Ayesha Minhas, Dr. Ayesha Sarwat, Prof. Atif Rehman, Dr. Dorothy Stubbe, and Prof. Muhammad Waqar Azeem. Once started, this fellowship will fill the much-needed gap in the training of child psychiatrists with adequate knowledge of

autism spectrum disorder and developmental disabilities.

In recent years, various parental groups have also played an important part in educating and supporting the families of children with autism spectrum disorder. The most well-known group in this regard is “Pakistan Autism Meet up,” which was established by one of the parents, Ms. Saira Salman, in 2003. This support group currently has hundreds of members across the country and around the world, including parents and health care professionals. This group was started in the city of Karachi and now has branches in Lahore, Rawalpindi/Islamabad, and Quetta, as well as an active online forum. Ms. Irum Rizwan and another volunteer, Mr. Qazi Fazli Azeem, along with several parents and volunteers, have played a considerable part in the ongoing success of this group as well as leading the advocacy efforts around the country. This group meets regularly and is instrumental in the support and services for ASD in Pakistan. Various nongovernmental organizations (NGOs) like Autism Spectrum Disorders Welfare Trust (a project of Mahvish & Jahangir Siddiqui Foundation with Ramaq Center for Awareness and Social Responsibility) are working to improve awareness regarding ASD all over Pakistan.

Future Directions

Unavailability of mental health law is an area in which Pakistan has not made much progress. At present, there are no federal laws related to services and education for individuals with autism and developmental disabilities. Sindh Empowerment of “Persons with Disabilities” Act, 2018, is perhaps the only such law at a provincial level, which specifically mention Autism as well as other neurodevelopmental disorders.

As noted above, there is much need for the establishment of a basic framework and integrated services for this population in need. This is why it is important for the public and private sector to join hands in providing comprehensive diagnostic, treatment, educational, and support services for these children and families in most need across the country. Authors believe that if we come together, the future is bright.

Palestine and Autism

Ramzi Shawahna

Department of Physiology, Pharmacology and Toxicology, Faculty of Medicine and Health Sciences, An-Najah National University, Nablus, Palestine

Historical Background

Since the end of the British mandate over Palestine in 1948 and the creation of Israel, the region has witnessed continuing territorial disputes, protracted violence, and political instability between the Arab Palestinians and the Israeli Jews. After the Oslo Accord signed in Washington, DC, in 1993, the Palestinian Authority was installed in the West Bank and Gaza Strip in a yet complicated peace process envisaging a two-state solution. Today, Palestine is a nonsovereign state that has been accepted as the 195th Member State by the United Nations Educational, Scientific

and Cultural Organization (UNESCO) in 2011 (UNESCO 2011). Palestine still holds a non-member observer state in the United Nations. The West Bank of Palestine is a landlocked area surrounded by Israel and bordered to the East by the Hashemite Kingdom of Jordan, while the Gaza Strip is 25 miles long and 4–5 miles wide land bounded by Israel and Egypt. The majority of the West Bank is controlled by Israel and a blockade has been in place since long limiting entry to and exit of Palestinians from the Gaza Strip. There are nearly 3 million Palestinians living in the West Bank and about 1.85 million living in the Gaza Strip.

Attention to autism spectrum disorders (ASDs) in Palestine has increased recently. This could be attributed to the increasing exposure to mass media, in part, and to the disseminated research carried out in the region and elsewhere around the world (Ashbee 2016; Dababnah and Bulson 2015; Dababnah and Parish 2013). This might have led to increasing the awareness of both healthcare professionals as well as laypersons on the issue of ASDs (Basha 2014). Tracking down the history of ASDs in this particular region of the world would be a difficult task in the absence of disseminated case reports. In addition, the incidence and prevalence of ASDs in Palestine are still unknown due to the absence of large epidemiological studies carried out for these objectives. Furthermore, Palestinian refugees in neighboring countries were excluded from studies conducted to determine the prevalence of ASDs, notably the one conducted in Lebanon although the number of Palestinian refugees in Lebanon registered by the United Nations Relief and Works Agency for Palestine Refugees in 2010 was approximately 440,000 (Chaaya et al. 2016). Recently, there have been calls to prioritize research needs in mental health in Gaza Strip and ASDs were among these priorities (Abu-El-Noor and Aljeesh 2014).

Probably, light was shed on ASDs when the Palestinian Bureau of Statistics has conducted its first specialized national disability survey in 2011 which included ASDs within the category of “learning difficulties” when the Palestinian Central Bureau of Statistics has conducted its first specialized national disability survey in 2011

which included ASDs within the category of “learning difficulties” (PCBS 2011). Prior to this disability survey, the Child Statistics survey made no mention of ASDs. However, next year (2012), the Child Statistics survey alluded to ASDs which were included within “learning disability/difficulty” (Ashbee 2016; PCBS 2012). Another light shedding event was the organization of the first conference related to ASDs which was held in April 2012 in Bethlehem to coincide with the World Autism Day (Ashbee 2016). The conference was well attended and policies were discussed. In April 2016, the An-Najah Child Institute of An-Najah National University took a next step and held another conference on “Autism Spectrum Disorder, Evidence Based Practices in Palestine.”

In Palestine, there are four main providers of healthcare to the Palestinians. These providers are: (a) the Ministry of Health (the public sector), (b) the private sector, (c) nongovernmental organizations (NGOs), and (d) refugee services operated by the United Nations Relief and Works Agency (UNRWA). NGOs provide many services including psychosocial support and rehabilitation for physical as well as mental disabilities. Utilization of the services provided by the NGOs accounts for 11% of the overall healthcare utilization in the West Bank (World Bank 2006). In spite of the reported dearth of services for children with ASDs in Palestine, some not-for-profit and NGOs provide services to individuals with intellectual disability and ASDs.

An-Najah National University, which is the largest university in Palestine, has established An-Najah Child Institute in 2013. This institute provides clinical, training, and research services related to ASDs. A comprehensive and multidisciplinary assessment approach is applied for the diagnosis of ASDs at this institute using internationally accepted tools which were translated into Arabic, adapted to culture, tested, and formally validated in Palestine. Currently, there is a kindergarten catering to the needs of children with ASDs. Once admitted, children are assessed, monitored, and individualized educational and skills acquiring plans are made for every child. Children with ASDs are grouped in small groups, each group of about five children and children

with high functioning ASDs are later included in classes with the mainstream educational programs along with other children without ASDs. The institute has many research initiatives and plans to use evidence-based practice in catering to the needs of children with ASDs.

The Jerusalem Princess Basma Centre for Disabled Children was established in 1965 initially as a home for children with physical disabilities. Later the center was opened to include both children with disabilities and those without disabilities. Today, the center offers services related to physical therapy, occupational therapy, speech therapy, and special education. Since 2011, the center offers services to children with ASDs (Jerusalem Princess Basma Centre for Disabled Children 2017). The center is unique in the Palestinian context. The staff at the center are well-resourced and trained in approaches for working with children with ASDs. The staff includes teachers and occupational and speech therapists. Unfortunately, Palestinians in the West Bank face difficulties accessing and utilizing the services offered at this center as it is located in East Jerusalem. Palestinians need to obtain a travel permit (a *laissez-passé*) from the Israeli authorities to enter Jerusalem. For Palestinians of the Gaza Strip, it is nearly impossible to utilize the services of the center as they are restricted to travel to Jerusalem by Israel (Dababnah and Bulson 2015).

Other centers catering to the needs of children with ASDs in Palestine include the Star Mountain Center which was started as a hospital and now offers services and cater to the needs of children with low-functioning ASDs and intellectual disabilities (Star Mountain 2017). Parents of children with ASDs established a community-based program known as Friends of Autistic Children Society (Friends of Autistic Children Society 2017). This center was established particularly for children with ASDs. Families of children with ASDs are closely involved. No formal training was provided to the staff; instead, they turned to the internet to seek guidance (Ashbee 2016).

Although the number of projects and programs that cater to the special educational needs of individuals with physical, intellectual, and learning

disabilities ran by not-for-profit organizations and NGOs has grown, many parents questioned the quality of the services provided and claimed the costs were unaffordable to a considerable percentage of those interviewed (Dababnah and Bulson 2015; Dababnah and Parish 2013; Nasir-Tucktuck et al. 2017). Rigorous data on the quality of screening, diagnosis, therapy, and other services available and accessible to individuals with ASDs in Palestine are still needed (Dababnah and Bulson 2015). In best practice, diagnosis of ASDs requires a comprehensive assessment which is carried out with the help of a multidisciplinary team using formally validated tools. Recent studies reported healthcare professionals lacking awareness and knowledge of ASDs (Dababnah and Bulson 2015; Dababnah and Parish 2013; Shawahna et al. 2017). In many cases, parents of children with ASDs reported noticing signs and symptoms of ASDs on their children before pediatricians. Parents also reported that pediatricians did not use any formal screening tools. Parents of children suspected of having ASDs struggle finding healthcare professionals trained to perform the diagnosis. Receiving inaccurate diagnosis and information on ASDs and being recommended to use treatments without a solid evidence for effectiveness have also been reported (Dababnah and Bulson 2015).

Traveling outside the country is a common practice by Palestinians seeking diagnosis and/or treatments of disorders including ASDs (Dababnah and Bulson 2015; Habash and Fteiha 2015). Obtaining a referral from the Palestinian Ministry of Health and a travel permit (a *laissez-passé*) from the Israeli authorities is often required for Palestinians to be allowed to visit Israeli hospitals and healthcare centers. Palestinians also often seek diagnosis and/or treatment in Jordan. Al Jabery and colleagues reported services including physical, occupational, and speech therapies available for individuals with ASDs in Jordan (Jabery et al. 2014). They also reported treatment services using hyperbaric oxygen and special nutritional plans. Extensive barriers to utilizing these services were reported, most notably, the cost. Geographic and political barriers also exist. Parents also reported challenges related to

checkpoints and transportation limiting their access and utilization of services related to ASDs. Beyond cost and geographic and political barriers, individuals with ASDs and their families often face a heavy burden of social and cultural barriers to access and utilize services pertaining to ASDs (Dababnah and Bulson 2015).

Legal Issues, Mandates for Service

The passage, in 1998, of the Right of Education for All law by the Palestinian Authorities led to reforms in teacher training programs and educational facilities to accommodate the different needs of students, including those with disabilities (Palestinian Ministry of Education 2000). Prior to this law, schools did not cater to the needs of school children with physical, intellectual, and/or learning disabilities (Nasir-Tucktuck et al. 2017). Following the passage of this law, progress has been witnessed in regards to changing the attitudes and perception of providing equitable education to school children with disabilities. In the last two decades, many grant-funded teacher training projects have been administered in the Palestinian territories and many new schools accepted students with learning disabilities and mild disabilities. Despite these efforts of inclusion, unfortunately many children with disabilities in Palestine skip education. According the Palestinian Central Bureau of Statistics, more than 1 out of 3 people with disabilities aged 15 and above had never been enrolled in any educational system and out of those who did enroll, nearly 1 out of 5 dropped out as a result of their disabilities (Ashbee 2016; PCBS 2011).

Financial assistance to individuals with ASDs and their families is limited. In Palestine, any person with disability is eligible to apply for support from the Ministry of Social Affairs. Eligibility for financial support is decided following an extensive scrutiny. Support consists of an amount equivalent to about \$215 every 3 months. This amount is hardly enough to cover the cost of diagnosis of ASDs. Financial restrains related to caring for children with ASDs in regard to treatment, vitamins, tests, diapers, costly specialty

items, speech therapy were reported by parents (Dababnah and Bulson 2015).

Overview of Current Treatments and Centers

Despite the dearth of services offered to individuals with ASDs in Palestine, the number of centers offering services to individuals with ASDs has grown recently. Some centers are striving to apply evidence-based approaches. Currently, the national mental health thematic group is developing the national policy for the diagnosis and treatment of ASDs. The policy was recently drafted and the formal approval is underway. Initiatives by parents and community-based programs have started and probably would be growing in the near future. Ambitious plans have been envisaged to create a village for individuals with ASDs (Ashbee 2016). However, these plans are beyond realization in the near future due to lack of funds and governmental support. Probably, this has come after the growing awareness of the importance of exposure to peers and acquiring of social skills.

Overview of Research Directions

Unfortunately, research programs are underdeveloped. Recently, some qualitative studies reported access to ASDs-related services as well as parents' perspectives of raising children with ASDs (Dababnah and Bulson 2015; Dababnah and Parish 2013). Another study investigated the awareness and knowledge of pharmacists on ASDs (Shawahna et al. 2017). A study investigated a possible link between iron deficiency and ASDs (Al-Ali et al. 2015). Another study sequenced whole exome and revealed complex inheritance patterns and identified two gene mutations implicated in ASDs and intellectual disability (Khalaf-Nazzal et al. 2016).

Large clinical trials are completely absent in Palestine as laws prohibited conduction of such trials. Recently, a law was passed which permits the conduction of clinical trials in Palestine. The passage of this law would probably open

new avenues for therapeutic interventions and research. Obviously, there is a dearth of interventional research in Palestine.

Overview of Training

The importance of training teachers to cater to the needs of children with ASDs has recently been recognized (Ashbee 2016). The Palestinian Ministry of Education has promised more commitment to develop in the field of education for children with ASDs. Resource rooms have been established in some schools to support children with additional needs. Some schools like the Friends school in Ramallah are including pupils with ASDs in the mainstream environment. The Jerusalem Princess Basma Centre for Disabled Children offers training to professionals in the West Bank in a trial to share experience and transfer know-how to their peers. More efforts are needed to accelerate the formal approval of the national policy for the diagnosis and treatment of ASDs and setting healthcare agenda in relation to ASDs.

Social Policies and Current Controversies

In a survey conducted in the West Bank by the Palestinian Central Bureau of Statistics, 1.6% of children aged 0–17 years were reported to have either physical or intellectual disability (PCBS 2011). It is important to mention that disabilities in the region are underreported and therefore, these figures should be interpreted with caution. Families with individuals with ASDs were reported to hide their afflicted siblings (Ashbee 2016).

Unfortunately, there is stigma in regards to individuals with disabilities in general. Social stigma and discrimination were reported by parents of children with ASDs (Dababnah and Bulson 2015; Dababnah and Parish 2013). Denial, depressive symptoms, poor coping, social isolation, and increased burden on siblings were also reported by parents of children with ASDs (Dababnah and Bulson 2015; Dababnah and Parish 2013). Parents

were able to cope with these challenges by religious practices, social support, and access to information. Fortunately, there is a growing body of information freely available on the internet that parents can access and learn about ASDs.

In Arabic speaking regions, words to denote disability are reported to be derogatory and pejorative. They are also used to swear. It is not uncommon for families to hide their children with disabilities fearing that the community will reject them.

A report by the Palestinian Central Bureau of Statistics on children and disability found that there is a tendency to blame the mother for her child's perceived disability (PCBS 2012). ASDs were often blamed as a "punishment from god." Recently surveyed pharmacist lacked adequate awareness and knowledge of and believed in myths in regard to ASDs (Shawahna et al. 2017).

Interestingly, today there is a louder parent voices demanding better governmental services for their children with ASDs. Increasing awareness and education might have an impact on reducing stigma and dispelling myths about individuals with ASDs.

Definition: Palliative Care for Adults with Autism Spectrum Disorders

The oldest cohort of adults with autism spectrum disorders (ASD) is aging, but little has been done to prepare for their end-of-life needs. A review of the literature does not reveal a substantial body of work on end-of-life care for adults with ASD. The purpose of this entry is to introduce caregivers and general clinicians who care for adults with autism to some of the unique challenges of palliative care in this population. It is also intended to familiarize palliative care specialists with some of the unique features of ASD.

There is tremendous variability in an autism spectrum that encompasses nearly every degree of functioning, but some issues in palliative care will be applicable to broad subpopulations of those with ASD. Obstacles related to patient autonomy will include communication challenges, decisional incapacity, and surrogate decision-making. First, some subgroups with ASD will express preferences and clinical guidance in atypical ways, and these communication mismatches can create challenges trying to manage pain and suffering in ways concordant with patients' wishes. Second, fear of dying, pain, and worry about an uncertain future are discomfiting in palliative care, generally, but may be exacerbated by features of autism that can lend themselves to a patients' isolation, confusion, or incomplete comprehension of what is going on around them. Broader issues will arise including the intertwined questions of decision-making capacity and surrogate decision-making. Some elderly adults with ASD will have full capacity to communicate long-term care plans, sign advance directives, and designate potential surrogates, while others will be able to do so only in a limited or attenuated manner. In these cases, surrogates will play integral roles in decision-making by augmenting and extending patients' self-determination; they will frequently be family members who have provided care for many years and now face new tasks that include shouldering the burden of surrogate decision-making at the end of life.

These challenges, and many further unfamiliar ones, will arise when elderly adults with autism enter palliative care settings. When these challenges do occur, strong psychosocial support and collaboration between caregivers, patients, and families will increase quality of life by ascertaining the preferences and goals of care of adults with ASD, thereby enhancing autonomy.

Historical Background

Palliative Care

Palliative care aims to improve quality of life for patients with serious or terminal illness and focuses on family-centered care designed to relieve suffering and increase comfort. Palliative

care originated in the modern hospice movement pioneered in 1967 by Dame Cicely Saunders (Fins 2006) and is initiated when "cure is no longer the prevailing goal of care" (Fins 2006). Comprehensive strategies for palliative care cover multiple domains of care, including physical, emotional, social, intellectual, and cultural needs. These domains can be addressed by interdisciplinary care teams that provide multidimensional management of symptoms; social, spiritual, cultural, and psychological support as ways of providing comfort and relief; and clear channels of communication between providers and families in order to provide support, acknowledge sensitive legal and regulatory issues, and resolve complex ethical challenges (The National Consensus Project on Quality Palliative Care 2013).

The domains of palliative care can be weighted differently. Some strategies of care "focus more comprehensively on the technical aspects of end-of-life care, such as drug dosing or the management of common symptomology" (Fins 2006). Other models emphasize the humanistic approach: a person-centered, shared-understanding model in which patients and physicians collaborate to understand disease trajectory and articulate goals about quality of life, intentions of care, and resolution of end-of-life issues (Fins 2006; Friedman et al. 2010). Humanistic models of palliative care aim to increase quality of life while keeping patient autonomy in the foreground.

As palliative care involves numerous decisions by patients and families, palliative care organizations seek to enhance access to information and choice. Short-term decisions include treatment preferences such as specifics of comfort care and pain management, location of care (e.g., hospital, hospice, or a patient's home), and which family members are wanted close at hand. Longer-term decisions dictate preferences that reflect the overarching values of the patient and how they want those values to guide or shape critical moments at the end of life. These include passive approaches to care, such as withdrawal of artificial nutrition and signing "Do Not Resuscitate" (DNR) forms, and active strategies including aggressive interventional treatment. Ideally, these decisions develop through ongoing conversations among patients, families, and providers, in which values

are articulated and expectations refined. After these conversations are completed, important procedures codify preferences into legally binding terms and documents, such as advance care plans that designate proxy decision-makers and treatment preferences in the event of decisional incapacity.

Adults with Autism Spectrum Disorders

Autism is a persistent developmental disorder with impairments in two broad categories: social communication and social interaction. Often diagnosed early in life, individuals typically exhibit restricted, repetitive patterns of behavior, interests, or activities (American Psychiatric Association 2013).

First identified in 1943 by pediatric psychiatrist Leo Kanner (1968), public awareness of autism increased during the 1950s and 1960s through now-discredited theories about “refrigerator mothers” as a cause, and diagnostic recognition expanded further with formal codification of autism in the 1980 publication of the DSM-III. Given this timeline, the oldest adults to receive a formal diagnosis of autism are in their late 50s, 60s, and early 70s. In many cases they have lived most of their lives with family or in supervised group homes.

Recent focus has been on early detection and early intervention in autism. Presently, children are diagnosed on average several years earlier than their counterparts 60 years ago, which allows for a greater amount of early intensive behavioral therapy during critical developmental periods (Howlin et al. 2014). However, this focus on early intervention has led to inadvertent neglect of adult and lifespan perspectives of older individuals with ASD: “We know next to nothing about people aging with ASD. There are...no data on the quality of life of the elderly with ASD” (Fombonne 2012). Emphasis on childhood autism has left gaps in care and services for adults with ASD.

Elderly adults with autism will face challenges that are extensions of childhood difficulties, as well as obstacles that are novel to old age. First, the core features of classical childhood autism extend into and take on new forms during adulthood. Children with autism who have modest or

higher IQ (≥ 70) in childhood remain relatively cognitively stable into adulthood (Seltzer et al. 2004). Some adults with autism are able to improve in their social and verbal skills and attain more stable social roles throughout adulthood, but this has been proposed to occur in a “splinter” fashion, with progress in discrete skills rather than improvement across the board (Seltzer and Shattuck 2003). Second, social interaction and communication deficits tend to lead to difficulties later in life in employment, independent living, and relationships and trouble with law enforcement for adolescents and adults with ASD (Volkmar et al. 2014), many of whom present with disadvantaged physical or mental health and overall quality of life as a result (Howlin and Moss 2012). As a result, 60–75% of individuals with autism have “poor” or “very poor” outcomes as adults (Seltzer et al. 2004; Howlin et al. 2014), but these tendencies vary based on the degree of early impairment, family support, and access to services. Trends in outcomes are likely more acute, i.e., a downward shift in function, in older generations of adults with ASD who have missed key therapeutic interventions that are now standard practice.

As diagnostic recognition has improved over time, the number of adults formally diagnosed with autism is expected to grow progressively larger. However, the prevalence of formal diagnoses likely underestimates the true rate of autism. The first comprehensive study to include undiagnosed adults found a relatively static rate of autism over time in the UK: 1.1% of 16- to 44-year-olds, 0.9% of 45- to 74-year-olds, and 0.8% of those 75-year-olds, roughly the same prevalence as the childhood population (Brugha et al. 2011). In many cases undiagnosed individuals with ASD were socially disadvantaged and unrecognized and did not access services.

Palliative Care Plans and Challenges (Current Knowledge)

The first group of adults with a formal diagnosis of autism is nearing the age when they might receive end-of-life palliative care. Features of autism vary in presentation among individuals,

so it is imperative to distinguish between individuals who are capable of articulating their vision for care procedures, those who will need support to do so, and those who might be cognitively incapable of doing so altogether. Providers should respond differently to these groups, tailoring their care, presence, and interactions to enhance self-determination and the quality of life of adults with ASD receiving palliative care.

As palliative care is a collaborative endeavor, providers can draw on various resources. The adult patient – the focus of care – has wishes, needs, and goals of care to be articulated. Family members and caregivers can be consulted as doing so can enhance the patient's communicative capacity and ability to make informed choices. There are also legal and ethical perspectives to take into account. It is in the spirit of palliative care to collaboratively address obstacles through open communication that involves all relevant parties in processes of decision-making and end-of-life choice.

Palliative care providers may face many challenges when caring for elderly adults with ASD, including:

Communication Differences

Communication is a prerequisite for choice and preference setting in palliative contexts. However, some adults with autism are unable to clearly articulate preferences and overarching values, which is an obstacle for palliative care personnel seeking to provide care in accordance with patients' wishes.

There is wide variation in verbal acumen of adults with ASD, reflecting the full breadth of the autism spectrum. By adulthood, many of those with partially or fully nonverbal autism will have identified noncanonical strategies for augmenting dialectical communication. Helpful strategies may include augmentative and alternative communication technologies (AAT) (Beukelman and Mirenda 2013), sign languages, physical or behavioral communication, facilitated communication, and visual communication such as PECS (Picture Exchange Communication System) (Dawson and Burner 2011). These mediums are used at different rates: 40% of people with ASD

use sign language, 26% use a high-tech assistive device (e.g., voice output system), 40% use a low-tech assistive device (e.g., Picture Exchange Communication System), and 95% reportedly use gestures (many individuals with ASD use more than one mode of assistive communication) (Gotham et al. 2015). These strategies may be adapted for a palliative care context; for example, social stories and books are used to communicate about the deaths of other people (The National Autistic Society: Death, Bereavement, and Autism Spectrum Disorders 2015), often older family members, but have not yet been extended to palliative care. Alternative communication techniques will play a crucial role in avoiding communication mismatch between palliative care providers and patients with ASD.

Understanding wishes conveyed directly by a patient is key, but in some cases adults with ASD may rely on caregivers who can assist in conveying a message. These intermediaries will often be able to aid in or facilitate the patient's own communication. Familiarity with alternative communication can help palliative care providers navigate complex clinical dynamics and ascertain the consent, choices, and preferences of elderly adults with autism, regardless of their verbal status.

Sensory Integration and Experience of Pain

Atypical sensory processing is a common feature of autism. It involves perception of tactile, auditory, visual, or painful stimuli as more or less noxious than their true intensity. Hyposensitivity to pain is troublesome in general medical contexts due to underreporting of illness, but hypersensitivity to pain is particularly worrisome as a primary goal of palliative care is the relief of terminal pain. Atypical processing of pain can severely affect quality of life and precipitate anxiety or agitation. In cases of pain hypersensitivity, there may be a need to adjust pharmacotherapy accordingly.

However, in cases of pain hypersensitivity, some adults with ASD will express desired strategies for pain management, while others will have difficulty with effective communication of internal experience. In the latter case, providers can

rely on nonverbal signs of pain and distress. These may include unexplained rises in heart rate and blood pressure or pupillary dilation, all signs of sympathetic overdrive. There are also behavioral observation techniques for assessing pain, such as the Critical Care Pain Observational Tool (Pun and Dunn 2007), which measures behaviors including muscle rigidity, body movements, and facial expressions, and the Adult Nonverbal Pain Scale (Rothman 2006), which can be used to assess pain and anxiety in critically ill, nonverbal adults by observing signs such as “stimming” or signs of overstimulation that can include grimacing, moaning, shaking, and hunched walking (Dell 2008). In short, effective terminal pain management for adults with ASD may necessitate awareness of nonverbal and physiological cues, nondialectical communication of discomfort, and potentially heightened importance placed on pain relief.

By communicating, patients can engage in the clinical decision-making process; however, communication alone is insufficient for robust choice. In some cases of ASD, beyond questions of communication and patient engagement, there will be additional concerns about the durability of the decisional process.

Decisional Capacity and Choice

Decisional capacity is the ability one has to make decisions for oneself. Insofar as decision-making relies on functional abilities that can be pathologically affected by certain disorders, in many cases it will be important to evaluate whether a patient has robust decisional capacity. Modern capacity evaluations focus on functional abilities-based criteria for capacity, typically the abilities to understand information relevant to a decision, appreciate the information (i.e., apply it to one’s own situation), reason with the information, and communicate a stable choice (Appelbaum and Grisso 1988). Other models of capacity assessment focus on whether the patient’s decision has been made in light of personal beliefs and values (Fins 2006).

Several features of decisional capacity are important to note. First, the threshold for capacity can vary depending on the decision at hand. The

“sliding scale” model of capacity articulates a threshold that varies depending on the consequences of a decision (Drane 1984). Thus, patients may be able to make some decisions but lack capacity for other, riskier ones. For example, a patient’s decision to sign a “Do Not Resuscitate” order should be subject to a stringent evaluation and a high capacity bar, but that same patients’ preference for some hospital foods over others needs not be questioned in the same way. A second, related point is that capacity “is not a global determination of cognitive abilities” (Fins 2006), rather, it is assessed for each *specific* decision in question. Thus, incapacity to make one highly complex medical decision should not be equated with incapacity for all decisions.

Some adults with ASD will meet functional capacity criteria to make weighty medical decisions, while others will not. Particularly those with Asperger’s, high IQ, or higher-functioning autism will have capacity to make medical decisions for themselves (Volkmar et al. 2005). Others with lower-functioning autism will lack decisional capacity, due in large part to comorbidity between autism and intellectual disability that occurs 17–70% of the time (Matson and Shoemaker 2009). However, even in cases of adults with autism who have severe intellectual disability such as mental retardation (MR), it will be important to evaluate patients and decisions on a case-by-case basis. “Most adults with mild and no mental retardation, and almost half of adults with moderate MR are able to make and justify treatment choices and fully or partially understand treatment information” (Cea and Fisher 2003). Additionally, 50% of individuals with mild MR, and 18 % with moderate MR, are able to “partially appreciate relevance of treatment choice to [their] situation and weigh treatment risks against benefit” (Cea and Fisher 2003).

Communicating with patients about their choices makes end-of-life care better. In palliative care settings, adults with autism should be presented with a full range of decisions including pain management, location of palliative care, and questions of comfort. As there is vast heterogeneity in ASD, no categorical state of capacity or incapacity will be found in elderly adults with

ASD in making palliative care decisions. Some adults with ASD will meet the threshold to set preferences about comfort care, but not to make a broader decision to withdraw life-sustaining nutrition. One method of ascertaining a choice if capacity is limited is to present possible options sequentially, such as possible locations of care, then allowing the individual to choose based on experience. When adults with autism have limited decisional capacity, communication between providers, the patient, family members, and surrogates will determine which elements of a care plan are best decided by the individual patient and which aspects should be decided by surrogates.

Adults with autism face obstacles to self-determination during palliative care. Many will have their decisions questioned or refused due to provider belief that the patient lacks capacity (Institute of Medicine 2006). A recent study of a Dutch residential facility retrospectively examined the files of 47 individuals with ID who had died during a determined span of time. Twenty-seven of these individuals had an end-of-life decision made about their care, and families were involved in only half of those decisions (Wagemans et al. 2010). There was also “no evidence in the notes that any of the people with IDs was asked for his or her own opinion in taking an end-of-life decision.” Palliative care providers, caretakers, and family members must ensure that the preferences of adults with autism are taken into account. Another challenge is the possibility of decisional conflict, which can arise among the patient, providers, and surrogates, when a patient with known limited capacity articulates a choice, but it is unclear whether they have capacity to make this particular decision. Finally, there may be disagreement among various proxies, each with legitimate claims to surrogacy. If this occurs, providers should seek out the legal surrogate. If none exists, a clinical ethics consult may be requested.

Surrogate Decision-Making

Surrogates and healthcare proxies may assume decisional responsibility for a patient who has been determined to have limited capacity or who cannot make independent judgments (Fins 2006). The goal of shared decision-making among

surrogates and palliative care teams is to reach decisions balancing the patients’ interests, medical needs, and goals of care. Decisions that surrogates may be called on to make include cessation of treatment and other difficult, emotionally demanding decisions. Since surrogate decision-making is not a simple task, guidelines (Fins 2006) aid proxy decision-makers in deciding on behalf of others: first, surrogates should make decisions in line with the “expressed wishes” of the patient, i.e., what the patient said they would want if they were ever in this scenario. If no wishes have been shared on the subject, it is appropriate to use a “substituted judgment” standard, i.e., how the patient “would have decided” if they were able to do so, which a proxy can determine in light of a patient’s preferences and values. Finally, in the “absence of information” on the patient’s desires, a decision can be made that is in the patients’ “best interest” (Fins 2006). Accurate decision-making on behalf of patients is a mechanism that helps patients extend their self-determination and autonomy in medical contexts.

Surrogate decision-makers for adults with autism will face challenges during palliative care. First, many adults with autism never express choices about palliative care, while others might do so but with suspect capacity. In these cases, a substituted judgment standard is ideal. Second, parents who have served as long-term caregivers are often best suited for surrogacy, but may no longer be living. In some of these cases, there will be court-appointed guardians who may be unfamiliar with the patient. Such guardians should consider that, under a “best interests” standard, the relative weighting of values and interests is unique for some adults with ASD. Even in cases of a long-standing surrogate who knows the patient well, deciding for others is a difficult, complex task, and others may have useful input. Family members, caretakers, guardians, group home staff, physicians, therapists, friends, and teachers may have extensive knowledge of the patient’s preferences and can assist in the decision-making process. Finally, when an adult with autism enters palliative care, surrogates may want to discuss potential issues with the care team and draw up plans in advance, in order to facilitate

decision-making during distressing, acute scenarios (King et al. 2004).

There are also legal hurdles in surrogate decision-making. Conflicting laws, practices, and principles can make it difficult to determine who should be making medical decisions (King et al. 2004). Family members and guardians of adults who have autism should always choose durable and valid healthcare proxies and codify these choices in proper documentation that is easily available.

Avoiding Futile Care

Not all medical care is good – there are harms of futile care. Medical futility can harm patients by causing unnecessary suffering with no possibility of direct benefit, injure the emotional state of a family, exhaust hospital resources, and put physicians in the uncomfortable position of having to provide care they know is ineffective (Fins 2006). Ideally, planning for futility questions takes place before futility questions actually arise and involves conversations between families, palliative care teams, and the patient.

Futile care decisions involving adults with autism raise at least two major considerations. One concern is that in the case of adults with autism, palliative care providers might worry about stigma of deciding that care is futile for vulnerable individuals, which can therefore lead to overtreatment and greater suffering. A second concern is that there may be an implicit presumption that adults with ASD and cognitive disabilities cannot participate at all in medical decisions, which would rob them of a voice. Obtaining assent and respecting dissent are both important when a patient has less-than-robust capacity. In particular, if pain sensitivity is a known concern for an adult with autism, assent and dissent may be highly informative as to treatment preferences and futile care. However, relying heavily on proxies to make decisions involving assent, dissent, and medical futility can place a severe burden on surrogates. Balancing these two considerations will require palliative care providers, families, and patients with ASD to draw up in advance ways of determining the point at which care might be futile for an individual patient.

Unique Palliative Care Comorbidities

Many unique challenges can arise during palliative care for adults with autism. First, several conditions frequently comorbid with adult autism, including anxiety (Bradley et al. 2004), depression (Ghaziuddin et al. 2002), ADHD, and epilepsy (Bailey et al. 1998), can create auxiliary complications. Some adults with autism rely on sameness and can be resistant to change, engendering anxiety as hospice is an unfamiliar setting, and as novelties such as an array of unfamiliar symptoms, tests, pains, and confusion are associated with many end-of-life scenarios. Anxiety can be mitigated in many ways, such as encouraging adults with autism to participate in the decision-making process regarding location of palliative care. There are also pharmacologic and non-pharmacologic techniques, including distraction, favorite rituals or practices, medication, art, and relaxation, that can help reduce anxiety and physical or emotional distress. Second, there is a risk that natural, somatic diseases go unreported among adults with nonverbal autism who are receiving palliative care. Communication deficits can make medical care more difficult or lead to diagnostic delay of various treatable diseases (Sea 2008). Adults with ASD may have increased or decreased internal sensitivity in addition to sensitivity to pain. These factors can make it difficult to assess and treat the secondary health status of adults with autism, especially those who are receiving palliative care focused on a primary condition.

Finally, adults with autism – particularly severe or nonverbal ASD – face a heightened risk that their own condition or care will be talked about in their presence by care providers, with the assumption that they do not understand the ongoing discussion. This would negatively affect the quality of life at its end, diminish the overall quality of care received by the patient, and violate principles of confidentiality and respect for persons.

Bereavement

Bereavement can come in many forms. Most elderly adults with autism will have experience with some form of death and may feel anticipatory grief, before death. For an adult with autism,

anticipatory grief may manifest in typical or atypical ways depending on the level of understanding of death and emotional engagement. There might be preconceived notions on the part of the patient of what a good death can or should look like. Palliative care providers should discuss and dissect these expectations, especially if they are inappropriately anticipated. Furthermore, many adults with autism live in group homes. If palliative care takes place in a group home, there is the possibility of grief or bereavement affecting other members of the group home, particularly those who observe the progression of care. Finally, in all cases, but perhaps most acutely those in which surrogates make decisions about futile care, providers should expect surrogate bereavement.

Future Directions

As the oldest adults with autism spectrum diagnoses begin to reach the natural end of life and receive palliative care, these adults, their families and surrogates, and healthcare providers will face novel challenges that require flexibility in care and communication. Future research should focus on understanding these challenges, including barriers to decisional capacity, how patients' capacity can be augmented to increase autonomy, and which issues most frequently arise during surrogate decision-making. What preferences do elderly adults with ASD express about the end of life, how are those preferences conveyed, and, most importantly, are they followed? Furthermore, how are the decisions surrogates face in palliative care substantively, emotionally, and psychologically different than the medical decisions they make for adults with autism earlier in life? Creative research programs are currently lacking and might conceivably be championed by national advocacy programs.

While palliative care has evolved profoundly as a field, further preparation will help care for adults with ASD at the end of their lives. Broad ethical issues can arise in palliative care including respecting preferences ascertained through consent, assent, or dissent so as to avoid under- or overaggressive treatment. Parents of children and adolescents with autism commonly express worry about an uncertain

future, particularly when they are no longer able to act as their child's surrogates. It is critical that parents or guardians, and adults with autism, take the time to have conversations during which values, preferences, and choices about the end of life are ascertained and formally codified to ensure legal authority. This will allow the palliative medical practice to bring its expertise in providing comfort to bear in a way that respects and honors the autonomy, capacity, and choices of an often-vulnerable population (Fins and Pohl 2015).

Paraeducator

► Paraprofessional

Para-educator

Karen Meers
Center of Excellence on Autism Spectrum
Disorders, Southern Connecticut State University,
New Haven, CT, USA

Synonyms

Aide; Classroom aide; Educational assistant;
Instructional assistant; One-to-one; Para;
Paraprofessional; Teacher's aide; Teaching assistant;
Tutor

Definition

Para-educators are school employees who work directly under the supervision of licensed professionals and who deliver instructional and direct services to students and their families. The licensed professionals, however, maintain responsibility for assessing learner and family needs and for planning, evaluating, and modifying programs. Pickett (1996) was the first to introduce the title para-educator to convey a level of training analogous to paramedic in the medical field and paralegal in the legal field. Historically, para-educators provided assistance with tasks ranging from clerical to individualized living tasks. In the present, they have become a key part of the specialized education team in delivering individualized instruction and services. Para-educators who work with children with autism spectrum disorders (ASD) and other developmental disabilities have responsibilities that may include assisting students with instruction; social, emotional, and behavioral skill development; and personal care. Additionally, they may also engage in behavioral data collection and collaboration with other educators (Rossetti and Goessling 2010). National Research Council (2001) lists para-educators as one of the potential resources for providing special services for children with autism.

Paralinguistic Communication Assessment

Sue Peppé

High Appin, Tynron, Thornhill, UK

Definition

“Paralinguistic communication” has been defined as “not WHAT you say, but THE WAY you say it.” Paralanguage, sometimes known as nonverbal communication, is communication by means other than words, although (usually) operating alongside language. Paralanguage is often impaired in people with autism spectrum disorder, to a lesser or, more often, greater degree than their language. Here, prosody (also known as intonation) and voice, which operate in conjunction with speech, are considered. More peripheral aspects of paralanguage would include eye-gaze, body language, and gesture: all often impaired in ASD.

“Prosody” is an umbrella term for modulations of the speech stream in terms of its loudness, length, and pitch. These modulations manifest themselves as the relative duration of syllables (determining speech-rhythm and speech-rate), the placing and quantity of stress in words, and changes of pitch (which produce pitch-patterns or contours). These affect the linguistic impact of utterances, conversational interaction, and the

verbal punctuation of speech; they also give indications of the speaker's identity (accent) and attitude to what is said. "Intonation" is another umbrella term for these modulations, which can also be described as "suprasegmental": "segmental" refers to the makeup of words in terms of consonants and vowels, and "suprasegmental" to levels which span individual sounds/letters, that is, generalizations that apply to syllables, whole words, phrases, and discourse.

"Voice" here denotes vocal quality, and the way this can affect the impact of the spoken word; for example, vocal huskiness suggests the imminence of tears and profound sadness in the speaker. Atypical vocal quality has often been noted in people with ASD.

"Assessment" refers to methods of gauging ability and the severity of disability. Assessment protocols range from procedures devised on an ad hoc basis for research projects to formal tests. Formal tests assess the degree, usually described in numerical terms, to which a speaker may be impaired on a particular aspect of speech. Such tests may be standardized, that is, provide data from large numbers of unimpaired speakers with which the performance of individual speakers can be compared.

Historical Background

Although the importance of prosody in speech has long been recognized, it was not until the 1980s that ways of assessing prosodic ability began to develop. Some protocols were devised as parts of investigations into speech impairment in conditions such as dysarthria or aphasia. These procedures were not comprehensive as tests of prosodic ability: They often assessed only a few aspects of prosody, for example, whether stress was placed correctly. Moreover, they focused on prosody in speech-production without assessing how well prosody was understood. They usually required transcription: A disadvantage, in that systems for transcribing prosody were (and are still) unsettled, and few people are familiar with them.

David Crystal designed a series of procedures for measuring disability in different aspects of

speech and language, one of which concerned prosody: This was known as "*Prosody Profile*" or "PROP" (Crystal 1982). The PROP sampled spontaneous speech which was prosodically transcribed and scored according to how correctly the prosody was deemed to reflect the speaker's intentions as to phrasing and conversational interaction. Since then, the PVSP (q.v.) has been devised, on lines similar to PROP in that it involves the sampling and transcription of spontaneous speech.

For the assessment of vocal quality, Laver devised the Vocal Profile Analysis (VPA) in the 1980s. This is a technique for assessing laryngeal, phonatory, and articulatory settings. Similarly, the GRBAS (Grade, Roughness, Breathiness, Asthenia, Strain) scale is used for evaluating hoarse voice quality.

There has been an awareness of prosodic and vocal impairment in autism since the earliest descriptions of the condition; in 1943, Leo Kanner, writing about children with autism mentions "a monotonous singsong manner" (Case 7) and a voice "peculiarly unmodulated, hoarse; utters her words in an abrupt manner" (Case 11). He also notes that in the repetitions (echolalia) of what was said to the children he examined "even the intonation is retained." Hans Asperger, writing in 1944, similarly observed odd prosody in the children with ASD that he examined.

The work of Christiane Baltaxe in the 1980s was pioneering in that it focused particularly on the assessment of expressive prosody in autism. See "References and Readings," McCann and Peppé 2003, for a review of articles addressing the issue and a description of assessment methods used. No publication has been made of the findings of the VPA and the GRBAS with speakers with ASD.

Current Knowledge

There are essentially four tests for assessing prosody and voice: one that assesses both, one devoted to prosody, and two to voice. There are also several other ad hoc procedures that have been used in research papers. Automated assessment is likely to increase: This will involve the collection of large amounts of speech-data which can be

scored in increasingly sophisticated ways by computer programs and will thus focus on prosody in speech-production as opposed to understanding of prosody.

Prosody and Voice

The *Prosody-Voice Screening Profile (PVSP)* assesses five suprasegmental speech factors (phrasing, rate, stress, pitch, and loudness) as well as two aspects of voice quality (laryngeality and resonance) in spontaneous speech for their appropriateness.

A major study used this test to compare the utterances of young people with ASD and typical development, and found inappropriate resonance and stress placement in the speakers with ASD (see “References and Readings”).

Prosody

The *Profiling Elements of Prosody in Speech-Communication (PEPS-C)* test assesses receptive and expressive ability in four functional aspects of prosody as well as auditory discrimination and imitation of prosody.

Several studies (see “References and Readings”) have used this test to research prosody in speakers with ASD, and have found impairment in some aspects, for example, the ability to place stress correctly, the use of prosody for conveying affect, and imitation of prosody.

Voice

Voice quality is assessed by making judgments about vocal sound, using adjectives such as “hoarse” and “husky” to describe it. Little has been done in the way of assessment of vocal quality in autism, and the standard diagnostic reference for ASD does not include vocal characteristics as a marker of ASD. As mentioned above, hoarse vocal quality was noted by Kanner in his first evaluation of autism. Vocal quality is generally taken as a good indicator of a speaker’s emotional and physical state, and hoarseness normally suggests tiredness or ill-health; this could be misleading if the hoarseness is part of the autistic condition. It is, however, true that listeners rapidly learn to discount the information value of habitual voice quality.

The Vocal Profile Analysis assesses laryngeal, phonatory, and articulatory settings, but no

publication has been made of its use with speakers with ASD.

The GRBAS (Grade, Roughness, Breathiness, Asthenia, Strain) scale is used for evaluating hoarse voice quality, but has apparently not been used for this in people with ASD. This scale was developed in Japan in the 1980s, but has no published standardized English protocol.

The Consensus Auditory-Perceptual Evaluation of Voice (CAPE-V) has recently been developed under the auspices of the American Speech-Language-Hearing Association (ASHA) and compares well with the GRBAS for reliability.

Automated Assessment

Programs have been developed to analyze speech automatically in terms of syllable-length, loudness, and pitch-variation. The advantage of automated assessment is that it can process very large samples, for example, of continuous day-long recordings. A disadvantage is that the programs have some way to go before they can accurately assess appropriateness for language use: Whether the variations of length, loudness, and pitch are typical of the language or accent being spoken, or adequately convey stress, phrasing, questions, etc.

Oller and associates (see “References and Readings”) have used such automated procedures with no human intervention; comparisons show that human judgment and automated assessment agreed well. They found that vocalizations of typically developing children and those of children with ASD were distinguished by spectral differences related especially to syllabification and by features of voice quality.

Van Santen and colleagues are also working on automated assessment. They have found that children with ASD show a difference in the balance between the various prosodic cues, such as pitch, amplitude, and duration, and not necessarily a difference in the strength or clarity with which prosodic contrasts are expressed.

Future Directions

Recent research suggests that certain prosodic functions are generally impaired in autism

spectrum conditions, for example, stress placement and the expression of emotion, and the understanding of prosody. It also seems that the degree varies more or less according to the severity of the autism condition. There is, however, scope for further research, for example in people with ASD who speak *languages other than English*.

A generalization in objective terms about the *acoustic characteristics of autistic prosody* has however proved elusive, although many people who work with autism would find it highly recognizable.

The period of time-consuming manual data collection and transcription for research purposes appears to be reaching its end, although this is still important for clinical investigation of individuals. In research, the manual process is being overtaken by *automation*.

The ability to understand prosody is central to language development and it seems that *prosodic processing* in the brains of those with autism may be different from non-autistic processing. Magnetic resonance imaging is being used to investigate this.

Assessment of Prosody in Other Languages

The PEPS-C test has been translated into French, Spanish, Dutch, and Norwegian, as described in Peppé et al. (2010). It is also available in various accents of English: UK General, UK Scottish, Irish, North American General, and Australian General. Requests for translated versions have been received from researchers working in Finnish, Portuguese, Farsi, Chinese, and Egyptian Arabic, and translation into more languages is a possibility.

Acoustic Characteristics of Prosody in ASD

The ability to generalize about the acoustic characteristics of prosody in ASD is still at an early stage. Diehl, Paul and colleagues found that their group of children with ASD had overall longer

utterance durations than children with learning difficulties and typical development, and that children with high-functioning autism show greater pitch variation in their speech (see “References and Readings” for details of this work). With increasing scope for acoustic analysis such generalization may be extended.

Automation

Having written nearly 20 years ago, Shriberg and colleagues regret that “completely objective measurement of all relevant parameters for prosody-voice assessment is currently not a technical option . . . use of inappropriate lexical, emphatic, and sentential stress, inappropriate intonation in pragmatic contexts, breathiness, nasality, denasality, and other parameters cannot be accomplished by current voice or speech recognition programs.” Assessment of prosody by automated acoustic analysis is increasingly available as technology develops, as indicated by the work of Oller and colleagues (see “References and Readings”). This focuses on the acoustic characteristics rather than the functions of voice and prosody: Their findings that atypical vocal quality and syllabification in children with ASD can be determined with automated analysis can be expected to contribute to early diagnosis and screening for ASD.

Prosodic Processing

There is increasing interest in using magnetic resonance imaging to establish whether there are differences in prosodic processing in the brains of people with and without ASD. Some differences have been found: for example, that in people without ASD the processing of speech sounds occurs in a different part of the brain than the processing of non-speech sounds, but that this is not the case in people with ASD; and that patterns of brain activation suggested a decrease of activation for emotional stimuli in people with ASD. For more recent research in this area, see the work of the Yale Center for Research in Autism and of Isabelle Hesling in Bordeaux, France.

Paraphasia

Margaret Millea

Department of Psychology, University of Notre Dame, Notre Dame, IN, USA

Synonyms

[Speech impairment](#)

Definition

Paraphasia is a speech disorder with neurological origins. Although the hearing and comprehension of speech may not be inhibited, the production of speech is not correct. The individual may be able to speak fluently, but with errors. The errors range from the mispronunciations of single words to the combination of words in inappropriate or meaningless ways. Because the sounds or words are mixed up, it may be difficult to understand the intended meaning.

There are three types of paraphasia:

1. Literal or phonemic paraphasia – incorrect phonemes are substituted. For example, one may say “spot” instead of “pot.” Literal paraphasia could also be switching syllables or creating reverse compound words such as “markbook” instead of “bookmark.”
2. Verbal paraphasia – saying a completely different word than the one intended. It could be a semantic replacement and be related to the intended word, or it could be remote with no clear connection to the intended word. An example of semantic verbal paraphasia would be saying “drive” instead of “car.” Remote verbal paraphasia would be saying “dog” instead of “car.”
3. Neologistic paraphasia – more than half of a word is incorrect. Out of context, it is difficult to guess what the intended word was. An example would be substituting “camalee” for “camera.”

Paraprofessional

Danielle Geno

The College of Arts and Sciences, The University of Vermont, Burlington, VT, USA

Synonyms

[Aide](#); [Assistant](#); [Associate](#); [Classroom aide](#); [Instructional assistant](#); [One-on-One](#); [Para](#); [Paraeducator](#)

Definition

Paraprofessionals are employees who, following appropriate academic education/instruction and/or on-the-job training, work with children

with disabilities, including those with autism, during the day to support their educational needs. The intention of a paraprofessional is to supplement the work of a teacher/service provider (American Speech-Language-Hearing Association 1999). The paraprofessional is becoming better known as a resource for providing services to the individual with ASD (National Research Council 2001).

Pareidolic Faces

Robert King
School of Applied Psychology, University
College Cork, Cork, Ireland

Synonyms

Asperger's; Autism Spectrum Disorder (ASD);
Face blindness; Mind reading; Prosopagnosia

Definition

Pareidolia is the overinterpretation of stimuli in the external world to impose patterns where none exist. This can apply to any sensory modality but is most commonly applied to visual stimuli. Within this realm, the term is often used to refer to the common human tendency to see faces where no faces are present. Familiar instances would include faces in the clouds, images of saviors in burnt toast, and the Man in the Moon (Liu et al. 2014).

Faces are perhaps the most socially significant visual stimuli encountered in the human environment (Palermo and Rhodes 2007). Autism spectrum disorder (ASD) is characterized by deficits in response to social stimuli (APA 2013). Thus, it has been hypothesized that those with ASD may be less susceptible to this illusion should neurotypical humans. Furthermore, it has been suggested that this feature may be used as a diagnostic tool to identify ASD at a relatively early developmental stage. Both of these hypotheses have received some empirical support.

In respect of the former, there is evidence that children with ASD do not pay particular attention to real faces (Kikuchi et al. 2009), at least not spontaneously (Guillon et al. 2016).

In respect of the latter, it has been found that children with ASD are less sensitive to pareidolic faces – that is, to objects that most people spontaneously report as possessing a face (Ryan et al. 2016).

Parent Expectations Mediate Outcomes for Youth with ASD

Anne V. Kirby

Department of Occupational and Recreational Therapies, University of Utah, Salt Lake City, UT, USA

Definition

“Parent expectations” is a term used to describe the beliefs parents hold about the likelihood their child will achieve certain outcomes. ASD literature on parent expectations has primarily focused on expectations about outcomes related to the transition to adulthood (e.g., participate in paid employment, live on their own without supervision).

Historical Background

Parent expectations have been widely studied in psychological and educational literature and have demonstrated relevance to a variety of youth achievement-related outcomes in many studies (e.g., Jeynes 2005; Yamamoto and Holloway 2010). The expectancy-value theory of achievement motivation, researched extensively by Allan

Wigfield and Jacquelynne Eccles (e.g., Wigfield and Eccles 2000), describes the role of expectations in informing outcomes and achievement in a wide range of areas. According to Wigfield and Eccles (2000), what individuals expect to achieve and what they value directly influence their efforts, persistence, decision-making, and, ultimately, performance. In this theory, expectations are also thought to be influenced by other personal and societal factors including demographics, the influences of others, gender stereotypes, and self-concept. As written, the theory articulates the role that one’s own expectations for oneself will have on their own outcomes. However, given the important role that parents play in the lives of youth with disabilities, this theory has been proposed to be extended to relate to parent expectations for their youth with ASD (Kirby 2016).

Current Knowledge

Scholarship over the past decade has suggested that parent expectations are relevant considerations for research related to the transition to adulthood for youth with ASD. Several studies using the National Longitudinal Transition Study-2 (NLTS2; IES n.d.) have provided evidence of the relevance of parent expectations during adolescence as important factors predicting outcomes for young adults with ASD. The NLTS2 involved data collection on over 11,000 US students receiving special education services in the year 2000 and involved 5 waves of data collection across 8 years. Students were ages 13 to 16 years at the start of data collection and 21 to 25 at the completion of the study (IES n.d.). In the NLTS2 survey, parent expectations for various young adult outcomes were measured using a four-point scale (i.e., definitely will not, probably will not, probably will, definitely will). Although the reasons are poorly understood, parents of youth with ASD in the NLTS2 reported among the lowest (i.e., least independent) expectations for young adult outcomes when compared with youth with other educational disability classifications (Newman 2005).

Using data from the NLTS2, Doren et al. (2012) identified parent expectations of future

employment (i.e., the likelihood that their child would eventually have a paid job) as a significant predictor of later employment for youth combined across multiple disability categories. Carter et al. (2012) also found parent expectations to be significant predictors of later employment for youth with severe disabilities (i.e., those eligible for alternative assessments at school). Both Doren et al. (2012) and Carter et al. (2012) looked at broader disability groups that included youth with ASD. With just the sample of youth with ASD in the NLTS2, Chiang et al. (2013) identified that parent expectations of future employment were able to significantly differentiate individuals with ASD who were later employed versus unemployed; however, this variable was no longer significant when included in a multivariate logistic regression model. Similarly, when looking at predictors of postsecondary educational participation, Chiang et al. (2012) found that parent educational expectations were able to significantly differentiate individuals with ASD who later participated in postsecondary education. This remained significant in a multivariate model, suggesting that parents who expected their adolescent child with ASD would participate in postsecondary education were 3.6 times more likely to have a child who did later participate. Across studies, higher parent expectations were associated with more independent outcomes for youth.

Using the NLTS2 sample of youth with ASD, Kirby (2016) applied structural equation modeling techniques to test parent expectations as a statistical mediator of outcomes in young adulthood. The key variables studied were family background (i.e., annual household income, maternal education, race/ethnicity), functional performance (i.e., self-care skills, academic skills, and social skills), and parent expectations about if their child will eventually have a paid job and live independently at the first data collection wave, as well as young adult outcomes (i.e., had a paid job and lived independently) at the final data collection wave. Kirby first ran a model that excluded parent expectations demonstrating how family background and functional performance variables in adolescence significantly predicted to later

young adult outcomes. Kirby then added parent expectations as a mediator into the structural equation model and found that the effects of both family background and functional performance were significantly mediated through parent expectations. In the updated model, neither family background nor functional performance directly predicted young adult outcomes; parent expectations were the only variable with a significant direct prediction of young adult outcomes (Kirby 2016). Kirby's (2016) findings suggest that both family background and youth functional performance significantly and directly predict parent expectations about if their child will get a paid job and live independently, which in turn significantly and directly predict young adult outcomes. This study suggested that although parent expectations have often been studied as predictors within regression models (i.e., independent variables), it may be more appropriate to conceptualize them as mediators (Kirby 2016). Furthermore, this study led to questions about if parent expectations causally influence outcomes or if they are an artifact of other causal influences.

Although Kirby (2016) demonstrated that parent expectations were mediators of outcomes for young adults with ASD, that study did not directly test possible reasons why this may be the case. The two leading hypotheses presented by Kirby (2016) were that (1) parents have a nuanced understanding about their child's future potential and (2) parent expectations directly inform the preparatory actions that parents and youth engage in to prepare for adulthood, thus leading to outcomes that are in line with expectations. Studies have since contributed new information about possible reasons – or mechanisms through which – parent expectations predict outcomes for youth with ASD. A qualitative study of parent expectations for 18 transition-aged youth with ASD suggested that as parents consider their future visions for their children with ASD, it can be difficult for them to disentangle expectations from hopes, fears, and uncertainty (Chen et al. 2018). Another qualitative study, by Kirby et al. (2019a), involved interviews with seven mothers of youth with ASD to examine how they had developed their expectations. Although not the

initial intent, the parents they interviewed also described the ways that their expectations have then influenced the ways they approached planning for the future with their youth. This result suggests that the expectations held by parents inform behaviors and decision-making that can then affect outcomes. For example, parents who believe their child is likely to be employed in young adulthood are more likely to encourage and help their child gain job-like experiences (e.g., chores, volunteer work) in adolescence, which will lead to them being more prepared for paid work. This directly ties back to the expectancy-value theory of achievement motivation (Wigfield and Eccles 2000) and its assertion that expectations influence decisions and behavior. These results also support Yamamoto and Holloway's (2010) hypothesis that parent expectations influence the extent to which parents engage in preparation for outcomes with their children.

Two papers lead by Holmes (Holmes et al. 2016; Holmes et al. 2018) looked at parent expectations as both independent and dependent variables to better understand the role they may play in the transition to adulthood for youth with ASD. These studies provide additional insight into the potential role that parent expectations play as mediators and also contribute to understanding of mechanisms that may explain how expectations influence outcomes. In the first study, Holmes et al. (2016) explored the role of parent expectations as related to parent-child sexuality communication for youth with ASD. They found that for youth with greater ASD symptoms, parents had lower expectations that they would have future romantic relationships and in turn reported having communicated about fewer sexuality-related topic areas with their child. Interestingly, parents of youth with ASD and IQ scores below 70 who did have expectations that their child would have healthy sexual relationships in the future reported having engaged in more parent-child sexuality communication. However, they did not see the same effect with youth who had average or above-average IQ scores (Holmes et al. 2016). In the second study, Holmes et al. (2018) found that greater ASD symptoms and IQ scores below

70 were significant predictors of lower (i.e., less independent) parent expectations for the future in the areas of financial independence, post-secondary education, citizenship, and independent living. When looking at the role of youth gender, parents of daughters with ASD had lower total expectations for the future compared to parents of sons. Since other factors were controlled for, this difference in parent expectations may be related to gender differences in societal expectations or different parental priorities for female versus male youth (Holmes et al. 2018). Holmes et al. (2018) also explored if parent expectations predicted transition preparatory activities, further extending the work to understand mechanisms described previously. They found that parent expectations predicted many of the transition preparatory activities they measured. For example, they found that parent expectations for the future predicted the likelihood that parents reported talking about jobs with their youth, providing chores or other responsibilities at home, and their youth's participation in life skills classes (Holmes et al. 2018). Both studies provide further support for the idea that parent expectations influence outcomes for young adults through the actions of parents (i.e., through a mechanism of decisions and behaviors).

In summary, the current state of research on the role of parent expectations as related to the transition to adulthood in ASD suggests that family- and youth-level factors (e.g., socioeconomic status and functional skills, respectively) inform the expectations parents develop for their child's future. Those expectations then influence decision-making and behaviors engaged in by parents and youth to prepare for adulthood. In turn, those preparatory actions, or lack thereof, lead to the independence-related outcomes of young adults with ASD (e.g., employment, independent living).

Future Directions

The existing body of research suggests that parent expectations for youth with ASD related to outcomes in adulthood have relevance for future

research and practice. Most critically, there is a need to understand the extent to which parent expectations during the transition to adulthood are changeable. If the expectations held by parents of youth with ASD are malleable, then it is possible that interventions to change parent expectations could have a positive influence on outcomes. A pilot study presented at the 2019 Annual Meeting of the International Society for Autism Research suggested that a group-based parent intervention, titled *Maximizing Adolescent Post-Secondary Success (MAPSS)*, resulted in modest increases in parent expectations after the 6-week program that were also maintained after 1 month (Kirby et al. 2019b). Additional work is needed to confirm that parent expectations are changeable through intervention and to determine if those changes are longitudinally associated with any improvement in youth outcomes.

There are also broader aspects of our understanding of parent expectations and their role in the transition to adulthood for youth with ASD that should be further explored. Notably, research on “parent” expectations in ASD typically has primarily measured the expectations of mothers. Expanding our understanding to include the expectations of fathers and the agreement or disagreement between co-parents and subsequent influences on outcomes will be important for the field. Additionally, more qualitative work and mixed methods research approaches with larger and more diverse study samples could uncover new aspects of the ways that parent expectations contribute to outcomes for youth with ASD. Finally, although the NLTS2 has provided an excellent resource for longitudinal research on this topic, the dataset is aging, and additional large, representative longitudinal studies could substantially further this body of research.

Parent attitudes toward genetic and epigenetic tests for ASD

Definition

Autism spectrum disorder (ASD) has many known genetic risk factors (Carter and Scherer 2013). As part of the comprehensive evaluation process for idiopathic ASD, genetic testing is recommended by the American Academy of Pediatrics (AAP) guidelines (Johnson and Myers 2007). Yet the cause of ASD remains unknown. Gene-environment interactions are believed to be involved in the etiology of the disorder (Lai et al. 2014). This has prompted interest in the epigenetic signatures unique to children with ASD. Epigenetic factors regulate gene expression in response to both internal (cellular) and external environments, but do not modify the actual DNA

sequence. There is potential for both genetic and epigenetic measurements to inform our biologic understanding of ASD and perhaps aid in ASD diagnosis.

Recent advances in biomedical research have demonstrated the potential for molecular testing to provide an early, objective, and accurate adjunct to childhood ASD diagnosis (Hicks et al. 2018, in press). Yet, parent perspectives toward genetic and epigenetic testing for ASD are not well-studied. It is imperative for scientists, clinicians, and the public to work collaboratively in assessing novel biotechnology that may impact medical decisions related to child health. The scientific community must take a collaborative approach to technology development, by understanding and incorporating parent needs and perspectives toward biological tests for ASD.

In a study investigating parents' understanding of genetics and epigenetics, concerns and attitudes toward ASD testing, and motives for participation in epigenetic research, 244 parents were administered a 16-question survey. To explore the influence of child developmental status on parental views, the study included parents of children with ASD (n = 131), non-ASD developmental delay (n = 39), and typical development (n = 74).

Parents had positive perceptions of genetic/epigenetic research in ASD. Most parents were strongly altruistic, indicating that "helping other children in the future" (85%) was the main reason for being involved in molecular research for ASD. Despite increasing public awareness about molecular technology (88% of parents were familiar with genetics), few fully understood how genetics differed from epigenetics (19%). Although parents did not doubt the scientific evidence behind genetic or epigenetic technology (0%), some had concerns about implications of genetic/epigenetic testing for ASD on privacy (14%) and insurance status (10%). The lack of a clear understanding of the science behind epigenetic testing did not impact parent interest. Most parents (95%) desired a molecular test to aid in ASD diagnosis when their child was 12 months of age or younger (71%). Surprisingly, overall interest in ASD testing and many of the parental perspectives reported

in the study were not dependent on child developmental status. Parents of typically developing children endorsed value in molecular testing, despite the absence of a child with ASD. The majority of parents (76%) desired a full return of genetic/epigenetic results, regardless of the known medical implications. This finding suggests a strong need for genetic/epigenetic tests to be ordered and interpreted by a healthcare provider, especially given the dichotomy between parents' understanding of genetic/epigenetic science and their desire for full results.

A molecular diagnostic aid for ASD has the potential to enhance the current behavior-based diagnostic process while addressing parent preferences for rapid, objective ASD assessment. It will be crucial that such a test carefully consider ethical, policy, and social challenges before introducing new technology to the healthcare system. It will also be important to consider the potential ramifications associated with the release of genetic/epigenetic information to parents, schools, and health professionals, as well as the policy implications surrounding treatment that might occur as a result of early, biologic ASD assessment. Understanding the motives, concerns, and wishes of parents regarding the development and delivery of genetic/epigenetic technology provides an ethical framework for translating molecular research into socially responsive medical advancement with the potential to benefit families and children with ASD.

Parent Responsiveness to Children at Risk of ASD

Jessica Lynn Kinard and Linda R. Watson
The University of North Carolina at Chapel Hill,
Chapel Hill, NC, USA

Definition

Marisa claps as her toddler, Stela, fits a star into the shape sorter. “Star!” Marisa says. Marisa offers her daughter another shape, but Stela shakes her head and pats the music player.

“Ah!” Stela says, glancing at her mother.

“Music?” Marisa asks. Stela grins at her, giggling. “Okay!” Marisa says. “Here’s the music!” She turns on a collection of children’s songs, singing as Stela dances to the music.

This interaction provides several examples of **parent responsiveness**. Parents demonstrate “responsiveness” when they: (1) recognize their child’s current focus of attention and (2) quickly respond to that interest in a positive and meaningful way, such as by playing with or talking about the child’s interest. Other qualities of “responsiveness” include being affectionate and animated,

offering praise and encouragement, sharing control of the interaction, taking conversational or play turns, and interacting within or slightly above the child's current developmental level. When parents use these behaviors that take into account their child's interests, communicative signals, affective state, and/or developmental level, they promote their child's further development in domains such as communication, social skills, and cognition (Landry et al. 2001). Because parent responsiveness fosters social interaction and communication, this topic is important to consider in the context of children with or at-risk for autism spectrum disorder (ASD), who demonstrate deficits in social communication. Based on the growing research in this area, this chapter will discuss the following topics: (1) the historical context of parent responsiveness, (2) current understandings of parent responsiveness to children at-risk for ASD, (3) ASD interventions targeting parent responsiveness, and (4) future directions.

Historical Background

Recognizing ASD as a biological condition is critical when discussing parent responsiveness. Historically, professionals blamed parents for causing autism, viewing the disorder as relationship-based, rather than biologically based. Decades of research now contradict this belief, indicating that ASD is caused by brain differences, rather than any way that parents interact with their child, but the harm to families has been deep and long-lasting. A brief review of this history is warranted to clarify how views of parent responsiveness in ASD have changed over time.

Parent-child relationships in the context of autism were first described by Dr. Kanner in 1943, who stated that the parents of these children were not "warmhearted." The idea of "cold" parenting took root in popular culture, leading to the harmful concept of "refrigerator mothers" – or the idea that children develop autism because of their mothers' frigid personalities. The "refrigerator mother" movement caused extreme harm to families, leading to parents being separated from their children, stigmatization, and feelings of guilt

(Feinstein 2011). In the 1960s and 1970s, parents and researchers questioned the validity of blaming autism on parent-child relationships and made discoveries that pointed toward biological causes of autism, ushering in the concept of an "autism spectrum disorder" (Feinstein 2011). In 2011, researchers discovered that infant siblings of children with ASD had an approximately 1:5 chance of developing ASD, as compared to 1:68 children in the general population, providing further evidence for the genetic nature of ASD (Ozonoff et al. 2011). Researchers also found that supportive and warm parenting styles in families with ASD are not inherently different than other families (Choi et al. 2019; Ku et al. 2019; Siller and Sigman 2002; Watson 1998). Meanwhile, advances in technology allowed for research into biomarkers of ASD, generating further findings that ASD involves neurological disruptions (e.g., Hazlett et al. 2017).

Although our understanding of what causes ASD is still unfolding, one point is clear: ASD is not caused by "cold" parenting. When considering parent responsiveness to children at-risk for ASD, then, it is critical to make the distinction between: (1) blaming parents for not acting "warm enough," an idea that is outdated and detrimental; versus (2) recognizing that parents are responding to their children in typical ways, but that the child's disorder impedes the process of a fluid social interaction. Interventions targeting "parent responsiveness" are not meant to "remedy" parent behaviors but rather to provide strategies to help parents overcome the social difficulties created by their child's ASD.

Current Knowledge

With this history in mind, the next section will detail what is currently known about parent responsiveness to children at-risk for ASD. The Transactional Model of Development posits that children's characteristics influence how parents act and, in turn, these parent behaviors influence children's development (Sameroff 2009). Using this model in the context of children at-risk for ASD, it is important to consider: (1) how early

characteristics of ASD influence parent responsiveness and conversely (2) how parent responses to children at-risk for ASD impact child development.

Impact of ASD Characteristics on Parent Responsiveness

Children are primarily identified as “at-risk” for ASD for two reasons: (1) the child has been flagged as “at-risk” during a developmental screening and/or (2) the child has an older sibling diagnosed with ASD, which increases the probability developing ASD. Research with each “at-risk” group provides insight into how children at-risk for ASD could influence parent responsiveness by demonstrating symptoms in one or both ASD diagnostic categories: (a) social interaction and communication impairments and/or (b) restricted and repetitive patterns of behaviors and interests.

Social interaction and communication.

Social communication impairments have been the most widely studied, in terms of their influence on parent-child interactions. Among typically developing children, strong communicators elicit more parent responses (Abraham et al. 2013). Communication behaviors among children at-risk for ASD similarly impact parent responses – the main difference, compared to typically developing infants, is how well children communicate. Infants at-risk for ASD tend to develop poorer social communication skills than low-risk infants, producing fewer consonant-vowel combinations (Garrido et al. 2017b), less sophisticated gestures, and fewer gestures overall (Choi et al. 2019; Wan et al. 2019). By 18 months, infants at-risk for ASD use: (1) one-eighth as many “pointing and showing” gestures as low-risk infants (Leezenbaum et al. 2014) and (2) significantly fewer gesture-speech combinations than low-risk infants (Choi et al. 2019; Wan et al. 2019). These types of gestures are considered sophisticated forms of communication, because they are later-developing and bring other people into a shared interaction (Choi et al. 2019; Paul and Norbury 2012). Because vocalizations and gestures both impact how parents respond, each will be described below.

Looking at vocalizations, an infant’s use of consonant-vowel combinations is important for eliciting responses. Parents of 9-month-old infants tend to respond more when their baby combines consonants and vowels (e.g., “bah-bah”), as opposed to only using vowels (e.g., “ah-ah”). This pattern is the same across low-risk and high-risk infants (Talbot et al. 2015); however, infants at-risk for ASD tend to produce fewer consonant-vowel combinations (Garrido et al. 2017b), use fewer directed vocalizations in a social back-and-forth manner (Garrido et al. 2017b; Swanson et al. 2017), and use fewer gesture-speech combinations than typically developing infants (Choi et al. 2019). Thus, infants at-risk for ASD may evoke less feedback from their caregivers because their vocalizations are often: (a) less sophisticated (i.e., vowels-only; not supplemented by gestures) and (b) not directed to others. Another way these vocalizations may impact parent behaviors is through prosodic matching: parents of typically developing infants tend to decrease their use of “motherese” (e.g., higher-pitched speech directed toward infants) between 12 and 18 months, whereas mothers of infants at-risk for ASD tend to increase the pitch of their voice, possibly in response to the slower development of sophisticated vocalizations among the high-risk group (Wan et al. 2019).

In addition to vocalizations, using more sophisticated gestures also encourages parents to respond more frequently. One way of responding to gestures is by “translating” the gesture – or putting the gesture’s meaning into words (e.g., saying “up” when infants raise their hands). When 13-month-olds have no family history of ASD, parents translate “giving and requesting” gestures (early developing) less frequently, instead providing more translations for “pointing and showing” gestures (later developing). However, parents of “high-risk” siblings translate “giving and requesting” gestures more frequently than parents of low-risk infants, while also providing translations for other gestures (Leezenbaum et al. 2014). Interestingly, parents of high-risk siblings who do not go on to develop ASD tend to gesture more frequently themselves, using gestures with a greater variety of meanings

than parents of low-risk infants or infants who later develop ASD (Wan et al. 2019). It may be that having an older child with ASD prompts parents to be more attuned to and/or more concerned about their younger child's communication, making them more likely to model a variety of gestures and translate all forms of their child's gestures, rather than selectively responding to more advanced gestures (Leezenbaum et al. 2014; Wan et al. 2019).

Another factor influencing parent responses is the child's ability to walk while gesturing. When typically developing 13-month-olds move while gesturing, mothers tend to direct the child's actions (e.g., "Throw the ball!"); however, if the child gestures while remaining stationary, mothers vary between offering affirmations, descriptions, directives, or no verbal response. Overall, mothers tend to provide: (a) more verbal responses to children who are walkers and (b) no verbal responses to crawlers (Karasik et al. 2014). Currently, it is unknown how the motor abilities of infants at-risk for ASD impact parent responsiveness; however, research examining motor skills sheds some light on this issue. When compared to low-risk infants, high-risk infants demonstrate poorer fine and gross motor skills from 12 to 36 months of age (Garrido et al. 2017a). High-risk infants who go on to develop ASD also tend to have poorer motor skills at 6 months of age (LeBarton and Landa 2019). Among 2- to 17-year-old-children with ASD, higher gross and fine motor skills are associated with better interpersonal skills (Mody et al. 2017). Collectively, these findings suggest a possible link between the development of motor skills and social communication. Because of these motor and social interaction deficits, it seems possible that infants at-risk for ASD would demonstrate difficulty gesturing while walking, reducing opportunities for parents to respond.

Thus far, we have discussed how the ability to *produce* communication impacts parent behaviors. Similarly, the ability to *understand* communication influences how frequently parents respond. Among typically developing infants and toddlers, parents talk about the child's interest more frequently if the child demonstrates greater

receptive language; unsurprisingly, this pattern holds true for toddlers and preschoolers with ASD (Watson 1998). Young children with or at-risk for ASD vary in their language skills but often demonstrate two patterns: (1) lower expressive and receptive language than expected (Garrido et al. 2017a; Paul and Norbury 2012) and (2) relatively weaker receptive than expressive language, suggesting that the foundations of comprehension supporting expressive language are less robust among young children with ASD (Paul and Norbury 2012). Along the same lines, the overall developmental level of children with ASD (e.g., cognitive and language skills) impacts parent-child interactions. Specifically, parents of children with ASD act more controlling when their children have lower developmental levels than expected for their age, possibly reflecting the extra challenge of parenting a child with both ASD and an intellectual disability (Ku et al. 2019).

Restricted and repetitive patterns of behavior. In addition to social communication, infants at-risk for ASD elicit different parent responses based on symptoms in the category of "restricted and repetitive patterns of behavior." This category has not received much attention in parent-responsiveness literature; however, available research suggests that the following behaviors could change parent-child interactions: unusual sensory patterns, activity levels, object play, and stereotyped behaviors.

One study has examined how patterns of sensory reactivity in 1-year-olds at-risk for ASD influences parent responsiveness (Kinard et al. 2017). In this study, infants were identified as "at-risk" for ASD based on a community screening, rather than family history, and elicited different types of behavior from parents, depending on their communication and sensory profiles. When children communicated less and were more hypo-reactive (i.e., exhibited diminished or delayed response to sensory stimuli), parents tended to respond by talking less and using more physical play actions. Conversely, when children communicated more and demonstrated less hypo-reactivity, parents responded with fewer physical play actions but more talking. Both the children's

patterns of sensory reactivity and communication accounted for unique variance in parent responsiveness. The authors speculate that parents of toddlers with hyporeactivity have learned that talking to their child fails to get his/her attention and so rely on physical play responses to engage the child (Kinard et al. 2017). Infants at high familial risk for ASD often demonstrate hyporeactivity (Van Etten et al. 2017); thus, this sensory pattern has the potential to be influential among families with infants at-risk for ASD.

Kinard et al. (2017) also found that a combination of hyperreactivity (i.e., overreaction or painful response to sensory stimuli) and communication skills influenced how parents responded to their children; however, the findings varied, depending on whether communication and hyperreactivity were measured via parent report or clinician observation, making it unclear how to interpret the results. Hyperreactivity in non-ASD populations could provide insight into how this sensory pattern impacts parent behaviors. When infants (not identified as at-risk for ASD) show tactile hyperreactivity, mothers tend to respond more with talking than physical touch and communicate from a farther distance than if their infant has no sensory difficulties (DeGangi et al. 1997). Parents of infants with sensory processing disorders also seem to have a harder time matching their responses to their infants' behaviors (DeGangi et al. 1997).

In addition to sensory patterns, children with or at-risk ASD may demonstrate additional behaviors that make the parent-child interaction difficult, such as low activity levels (Wan et al. 2012), high activity levels (Meek et al. 2012; Watson 1998), wandering without engaging (Watson 1998), overfocusing on one toy (Watson 1998), less functional object play (e.g., spinning objects, visual examination) (Kaur et al. 2015), or producing large amounts of undirected vocalizations, which may function as an early repetitive or stereotyped interest (Swanson et al. 2017). Parents of children with ASD respond in a warm, supportive manner to their child as frequently as parents of typically developing children. However, parents of children with or at-risk for ASD also tend to manage their child's behavior more frequently

(Meek et al. 2012; Ku et al. 2019; Wan et al. 2012; Watson 1998) and demonstrate more negative behaviors, such as dismissing the child's ideas (Ku et al. 2019). These differences in behavior management have been seen as early as 7 months (Wan et al. 2019) and might reflect an attempt to stimulate, focus, or expand the children's play repertoires (Watson 1998). In the case of younger siblings, it may also be that parents have developed a directive style based on interactions with their older child with ASD, which they now use with their infant, or they may be experiencing stress from parenting an older child with ASD that contributes to the expression of negative behaviors and/or influences how much they direct their infant's behaviors (Ku et al. 2019; Wan et al. 2012). The relationship between parental directive actions and children's restricted and repetitive behaviors needs to be examined in future research.

Impact of Parent Responsiveness on Children at-Risk for ASD

With an understanding of how a child's ASD characteristics could influence parent responses, this section will discuss how, in turn, parent responsiveness could impact children at-risk for or with ASD. The role of parent responsiveness on child outcomes can be viewed in three ways: (1) intensity level and consistency over time, (2) type of response and how well the response "matches" the child's current needs, and (3) parent responses in the context of parent-implemented interventions. Each of these aspects will be discussed below, in terms of how they contribute to child outcomes.

Intensity and consistency of parent response. The intensity and consistency of parent responses is crucial for achieving optimal child outcomes. Parents who are highly responsive spend much of their interactions: (1) observing their child to determine his/her interests or communication attempts and (2) quickly responding to the child's actions in a way that is supportive, affectionate, meaningful, and appropriate to the child's current interests and abilities. Parents who are consistently responsive will maintain these high levels of responsivity from infancy through

childhood. When parents demonstrate a combination of high-intensity and consistent responsiveness, their children are likely to develop stronger cognition, communication, and social skills than if parents provide low or inconsistent levels of responding (Landry et al. 2001). Children can still benefit from periods of high-responsiveness if parents are inconsistent in maintaining these levels (e.g., highly responsive during infancy but minimally responsive during preschool years); however, such inconsistent responsiveness is not as effective as consistent responsiveness in supporting children's long-term cognitive, linguistic, and social gains (Landry et al. 2001). Inconsistent patterns of responding could occur for many reasons, such as (a) beliefs about what children need as infants versus as preschoolers (Landry et al. 2001) and/or (b) characteristics of the child that make it increasingly difficult to respond, as described earlier in this chapter.

Type and developmental “match” of parent response. In addition to intensity and consistency, children achieve different outcomes depending on: (a) the type of parent response and (b) how well this response matches the child's current needs. Parent responses are often divided into two categories: (1) physical actions and (2) verbal feedback. Physical actions are defined as play actions or other physical movements parents use in response to the child's focus of attention (e.g., imitating actions, demonstrating new actions, helping the child, pointing to or showing objects, or providing encouragement or affection in a physical way). Verbal feedback is defined as talking in response to the child's current focus of attention (e.g., verbally imitating, expanding, labeling, translating gestures, describing, affirming, and directing or prompting).

When defining verbal responses, a distinction should be made between “nondirective,” “directive,” and “re-directive/intrusive” verbal behaviors. Nondirective verbal feedback involves commenting on a child's interest without directing his/her actions (e.g., “That's a cow”). In contrast, directive verbal feedback is responsive to the child's interest but requires that the child change his/her behavior (e.g., “Put the cow in the barn”).

Redirections or “intrusive” comments are not considered directive feedback, because they are unresponsive to any aspect of the child's attention (e.g., “We're done with the cow, let's read a book”) (Siller and Sigman 2002). Directive feedback is beneficial for both children with typical development and ASD, as long as parents are responding to the child's focus of attention (Masur et al. 2005; McDuffie and Yoder 2010); thus, both directive and nondirective feedback will be included in this discussion.

Children seem primed to benefit from a variety of verbal and physical responses that are well matched to their current needs. Around 9- to 10-months-old, infants make gains in motor skills and intentional communication that allow them to crawl and explore their environment, manipulate objects in more advanced ways, and initiate social games (Kaur et al. 2015; Paul and Norbury 2012; Wan et al. 2012). For example, infants at low-risk for ASD begin purposefully dropping objects around this age to explore sound effects and initiate social games with their parents (Kaur et al. 2015). Infants often imitate their first words sooner when parents describe these exploring behaviors (Tamis-LeMonda et al. 2001). In contrast, infants at-risk for ASD demonstrate less activity, movement, and object manipulation at this age (Wan et al. 2012) and are less likely to drop objects to initiate social games (Kaur et al. 2015). As detailed earlier, parents of infants at-risk for ASD tend to redirect their children more frequently, possibly due to the lack of functional play and presence of stereotyped or repetitive behaviors that make it challenging to respond. The impact of these directive behaviors is unclear; however, among infants with familial risk for ASD, parent responsiveness has been associated with more frequent parent-directed smiles, whereas directiveness has been associated with slower development of directed smiling between 9 and 18 months of age (Wan et al. 2019). Similarly, research with typically developing infants indicates that *responsive* directive behaviors are associated with positive language outcomes, but *intrusive* directive behaviors are associated with smaller vocabulary growth (Masur et al. 2005).

In addition to motor and object exploration, 9- to 10-month-olds are making advances in their vocalizations, babbling with consonant-vowel combinations to engage in back-and-forth social interactions (Paul and Norbury 2012). When parents respond to vocalizations at this age, infants seem ready to learn vocabulary, saying their first words sooner when parents provide: nondirective verbal feedback (e.g., describing, affirming), directive verbal feedback (e.g., prompting play), and demonstrations of play actions. Directive feedback (e.g., prompting play and demonstrating play actions) also helps children acquire more vocabulary and combine words at earlier ages (Tamis-LeMonda et al. 2001). When compared with low-risk infants, infants at-risk for ASD produce more vowel-only vocalizations, less social babbling, and fewer conversational turns (Garrido et al. 2017b; Swanson et al. 2017), possibly eliciting fewer or different parent responses (Talbot et al. 2015). More research is needed to explore how this dynamic impacts later child outcomes; however, infants at-risk for ASD may be missing verbal and/or physical feedback that could be beneficial for later vocabulary development.

Between 10 and 12 months, infants advance from babbling to word attempts (Paul and Norbury 2012). Responses that support early word imitation become important for later language outcomes. At 10 months, children's language seems most supported when parents respond with physical actions, as opposed to verbal responses. When parents physically respond in a way that matches the child's interests, engages them in an interaction, and is meant to help the child learn, infants tend to have larger expressive vocabularies at 13 months of age (Masur et al. 2005). In contrast, infants have lower expressive vocabularies at 13 months if their parents were very talkative at 10 months (Masur et al. 2005). Shorter utterances and more physical play actions may better match children's current abilities than "streams" of talking, which could be hard for 10-month-olds to process (Masur et al. 2005).

Around their first birthday, infants reach new milestones in communication, motor skills, and play, allowing them to benefit from parent

feedback in more complex ways. In terms of verbal communication, 1-year-olds say their first nonimitated words, which are formed with consonant-vowel shapes and can be used in conjunction with pointing to comment on objects (e.g., saying "ba"/ball while pointing to a ball) (Paul and Norbury 2012). Whereas physical responses seem most influential at 10 months, verbal responses become most powerful at this new stage, scaffolding 1-year-olds' attempts at word production. Types of verbal responses that seem most beneficial include: (a) verbal imitation, which helps children build their vocabulary; (b) verbal imitations, expansions, and play prompts, which help children combine words sooner; and (c) asking questions, which (along with verbal imitations and expansions) help children learn to talk about the past (Masur et al. 2005; Tamis-LeMonda et al. 2001). When compared to parents of low-risk infants, parents of infants at-risk for ASD make smaller increases in how much they respond to their infant's vocalizations over 13–18 months of age (Leezenbaum et al. 2014), possibly because of the nonsocial and unsophisticated nature of their child's vocalizations (Garrido et al. 2017b). More research is needed to examine how reduced verbal feedback at 1 year of age could impact child language outcomes; however, these limited parent responses could have negative implications, given the power of verbal input at this age.

As more sophisticated gestures emerge around the end of the first year, parents are prompted to "translate" the gesture's meaning into words (Leezenbaum et al. 2014). In turn, these translations help children develop more vocabulary, such as (a) more nouns by 17 months when parents translate "commenting" gestures with object-labels and (b) more verbs by 17 months when parents translate "requesting" gestures with action words (Olson and Masur 2015). Similar patterns have been found for infants at-risk for ASD. Both infants at low- and high-risk for ASD produce more words at 18 months when their parents translate "pointing and showing" gestures at 13 months (Leezenbaum et al. 2014). In addition to these verbal responses, parents who share positive affect with their 12-month-old seem to foster

more positive affect from their child in return, along with more child vocalizations, gazing at faces, and combinations of communicative means, regardless of risk status for ASD (Schwichtenberg et al. 2019).

As typically developing toddlers approach their second birthdays, they experience a language burst, producing 50–100 words by 18 months, combining words, and needing less contextual support to understand language (Paul and Norbury 2012). Children seem able to process more complex verbal feedback at these older ages, developing a larger subsequent vocabulary when parents provide verbal descriptions and expansions (e.g., Child: “Shoe”; Parent: “Mama’s shoe”), as opposed to simply imitating the child’s vocalization (Masur et al. 2005). Responding with physical actions also helps children develop larger vocabularies (Masur et al. 2005). When children with ASD attempt to communicate, parents respond with nondirective and directive verbal responses, both of which help children increase their vocabulary (McDuffie and Yoder 2010). Similar to typically developing children, expanding the communication attempt of a child with ASD, as opposed to simply imitating, seems to have a greater impact on vocabulary outcomes 6 months later (McDuffie and Yoder 2010). This verbal feedback appears most beneficial when parents adjust the complexity of their verbal input to the child’s current language. When toddlers with ASD are minimally verbal, nondirective verbal feedback is associated with language gains; however, these same benefits are not seen for verbally fluent toddlers with ASD (Haebig et al. 2013). It may be that simplistic verbal input that supports language in minimally verbal toddlers with ASD is not sufficiently complex to scaffold the language of toddlers with ASD with more advanced language skills (Haebig et al. 2013).

Along with communication, toddlers are expanding their play repertoire and ability to pay attention, so that, by 18 months, they are playing simple pretend games and following one-step commands with minimal contextual support (Paul and Norbury 2012). Parents who respond to their child’s focus during play, as opposed to redirecting the child, continue facilitate their child’s language-

learning during the toddler stage (Masur et al. 2005). Although redirections negatively impact vocabulary development, parents who direct their child’s attention seem to be providing examples of how to initiate an interaction, making it more likely that their child will also initiate joint engagement (Meek et al. 2012). In contrast to the play skills and attention levels of typically developing toddlers, toddlers at-risk for ASD continue to mouth objects at 15 months, may only be beginning to use objects with functional ways, and demonstrate limited social attention (Kaur et al. 2015). As long as parents respond to their child’s focus of attention, both directive and nondirective verbal responses to children with ASD have been associated with greater short- and long-term increases in social communication and language (Haebig et al. 2013; McDuffie and Yoder 2010; Siller and Sigman 2002, 2008). Similar to typically developing populations, when parents model how to point to or show a toy, children with ASD tend to initiate joint attention more frequently (Meek et al. 2012; Siller and Sigman 2002).

Thus, for both low-risk infants and infants with or at-risk for ASD, children achieve positive language outcomes when their parents respond to the child’s focus of attention, adapting these responses over time to match the child’s current developmental needs. It is encouraging that responsive parenting helps children with ASD make long-term gains in social and language skills; however, it is also critical to note the challenges that parents face when trying to establish responsive parent-child interactions. To address these needs, researchers have developed parent-implemented interventions for infants and toddlers with or at-risk for ASD, designed to achieve two main outcomes: (1) enhance parent responsiveness through interventionist coaching and (2) improve child outcomes through parent use of responsive strategies. A brief review of parent responsiveness interventions is provided below.

Parent responsiveness interventions. Parent-implemented interventions for ASD have been identified as evidence-based practices by both the National Professional Development Center on Autism Spectrum Disorders (NPDC; Wong et al. 2015) and the National Standards Project

(NSP 2015). Examples of early ASD interventions that include a “parent responsiveness” component are listed in Table 1, along with examples of targeted child outcomes and parent strategies. These types of programs may be most successful

for children at early stages of language development (Siller and Morgan 2018). Although each intervention program offers unique content to families, they share many common goals and strategies. A complete review of parent

Parent Responsiveness to Children at Risk of ASD, Table 1 Examples of parent-implemented interventions incorporating parent responsiveness strategies

Examples of interventions	Examples of child goals	Examples of parent strategies	Reference
Preschool Autism Communication Trial (PACT) intervention	Shared attention; initiating communication; communicating for a variety of reasons; pragmatics	Match parent language to child’s level; interpret child’s behavior as intentional communication; follow child’s lead; provide verbal imitations and expansions; motivate child to communicate with “teasers” or “sabotage”	Green et al. (2010)
Enhanced Milieu Teaching	Word combinations; requesting	Provide verbal imitations and expansions; follow child’s lead; match parent language to child’s targeted level; balance turn-taking with child; provide milieu prompts (e.g., modeling, time delay); give positive feedback	Kaiser et al. (2000)
Joint Attention, Symbolic Play, Engagement, and Regulation (JASPER) intervention	Joint engagement; initiating and responding to joint attention; functional play; symbolic play	Follow child’s lead; imitate child’s actions; describe child’s actions; provide imitations and expansions; give corrective feedback; arrange environment to facilitate engagement (e.g., face-to-face with eye contact)	Kasari et al. (2010)
Joint Attention Mediated Learning (JAML) intervention	Focusing on faces; turn-taking; responding to joint attention; initiating joint attention	Play face-to-face games with vocalization; imitate child gestures; interpret child’s behavior as meaningful communication; join child’s repetitive play; follow child’s lead; pause for child response; play teasing games; create animation, excitement, and suspense; offer “surprises”	Schertz and Odom (2007)
Responsive Teaching (RT)	Cognition; communication; social-emotional functioning	Match responses to child’s developmental level, interest, and behavioral style (e.g., follow child’s lead); create reciprocal interactions (e.g., play face-to-face games without toys); share control (e.g., wait silently for a more mature response); provide contingent feedback (e.g., respond to unintentional behaviors as if meaningful conversation); demonstrate positive affect (e.g., respond to child in playful ways)	Mahoney and MacDonald (2007)
Adapted Responsive Teaching (ART)	Social communication; sensory-regulatory behaviors	Incorporates similar strategies as RT intervention, but uses strategies to target social communication and sensory-regulatory behaviors	Watson et al. (2017)

responsiveness interventions is out of the scope of this current chapter; however, further details and videos of several interventions can be accessed on the following websites: (a) the NPDC evidence-based practices page (<http://autismpdc.fpg.unc.edu/evidence-based-practices>), (b) the ASD video glossary on the Autism Navigator website (<http://resources.autismnavigator.com/>), and (c) the Autism Internet Modules (AIM) website (<http://www.autisminternetmodules.org/>).

Based on current research, recommendations have been proposed to make parent responsiveness interventions as successful as possible. These recommendations include the following: start intervention as soon as risk for ASD is identified; target a variety of developmental domains; adjust goals and strategies to match the child's changing developmental needs; provide parent coaching for at least 9–12 months, including both video feedback and direct, hands-on instruction; allow parents to learn strategies in small doses and in a structured environment; practice strategies in multiple settings and in daily routines to support generalization; include booster sessions to refresh learning; consider using augmentative and alternative communication (AAC) to support language development in children with speech delays; include both professional- and parent-delivered intervention components; and ensure that the intervention is implemented with fidelity (Landa 2018).

Summary and Future Directions

Parent responsiveness is critical for helping children with or at-risk for ASD develop social, communication, and cognitive skills. From a transactional framework, early symptoms of ASD impact how parents respond to their child; in turn, these responses influence child outcomes. Children with better communication skills elicit more responses from parents; however, children at-risk for ASD commonly exhibit deficits in social, communication, and motor skills that may limit how parents respond. Restricted and repetitive patterns of behavior also make parent-

child interactions more challenging for parents. Despite these challenges, parents help their children develop important skills when they: (a) frequently respond to their child's focus of attention, (b) limit how much they redirect their child's attention, (c) maintain these high levels of responsiveness across infancy and childhood, (d) provide a variety of verbal and physical responses that align with the child's skill level, and (e) adapt these responses over time to meet the child's changing needs. Based on the benefits of parent responsiveness, parent-implemented interventions for children with or at-risk for ASD have been developed to: (a) help parents overcome challenges in parent-child interactions and (b) improve child outcomes through enhanced parent responsiveness. Researchers are continuing to study these interventions, so that programs can be tailored to families' needs.

Although parent-implemented interventions have a strong evidence base, researchers are continuing to examine the effectiveness of these interventions for infants and toddlers at-risk for ASD. Interventions have been successful at enhancing parent responsiveness and parent-child interactions, but have achieved varied outcomes for children. These varied outcomes may stem from initial characteristics of the child and family, differences in study design, and/or the fact that there are a wide variety of intervention programs that incorporate parent responsiveness strategies, making it difficult to determine which intervention components are most successful and for whom (Edmunds et al. 2019; Oono et al. 2013; Shalev et al. 2019; Siller and Morgan 2018). Because of these varying outcomes, the field is moving toward an ideal of "tailored" intervention approaches, where programs can be matched to families based on their initial characteristics. For future research, it will be important to reach a consensus on which "active ingredients" are most effective at supporting child outcomes across a variety of parent-implemented intervention programs. It will also be beneficial to examine initial child and family characteristics in at-risk populations and the extent to which these characteristics predict long-term treatment outcomes.

professional delivering the training, and the targets of the PT. The term “PT” has also been used interchangeably with parent management training, parent effectiveness training, parent-mediated training, and parent-assisted training depending on the target group and foci of treatment goals. PT as a model of service delivery has been described extensively in numerous fields to include the mental health and psychological sciences, education, and health sciences. Broadly defined, PT involves teaching parents and caregivers knowledge and skills to more distally impact a child. The specific content and format of PT may vary, as does the delivery and duration of the program. PT programs may include sessions on child development, behavior management, communication, and interaction styles but more specific skills such as increasing a child's compliance to a medical regimen. PT may be delivered individually, in group setting, and via distant learning mediums (Internet, DVD). For purposes of PT related to autism spectrum disorders (ASD), PT assumes parents are taught to intervene with their child with ASD to decrease challenging, interfering behaviors (e.g., aggression, disruptive behaviors) and/or to teach new behaviors. These new behaviors may be directly related to core and early emerging deficits (e.g., social communication behaviors) but also developmentally appropriate skills (e.g., preacademic skills) and self-help, adaptive skills.

Parent Training

Cynthia R. Johnson¹ and Johanna Patricia Taylor²

²Pediatrics and Education, University of Pittsburgh, Pittsburgh, PA, USA

Definition

Over the past 40 years, parent training (PT) has been defined to have slightly differing meaning depending on the intended population, the

Historical Background

As already suggested, teaching parents in the concepts and skills to in turn impact their children's behavior has a long history for a range of childhood issues. PT is a well-established intervention for children with noncompliance and disruptive behaviors. PT, often referred to as parent management training for these populations, has been studied for children with attention deficit/hyperactivity disorder (Barkley et al. 2001) and conduct problems (Kazdin 2003). PT has more recently been demonstrated to be a promising treatment mode for childhood anxiety disorders (Barrett and Shortt 2003) and for tics and Tourette's

(Scahill et al. 2006). PT training during the preschool years to offset the sequelae of childhood behavioral issues has been an active area of inquiry as well (Eyberg et al. 1995; Webster-Stratton and Taylor 2001). Further, PT as treatment or prevention of child abuse is a well-recognized approach (Lundahl et al. 2006).

PT also has a long tradition for children with developmental delay and intellectual disability (ID) broadly defined. Parent involvement is generally accepted to be particularly critical for improved outcome in this population. Baker and colleagues have been instrumental in establishing parent training as an efficacious approach for children with a range of ID (Baker 1996; Baker et al. 1997). Parent training in this line of work focused on teaching parents basic behavioral principles to improve behaviors as well as teaching procedures to promote skill development. Other lines of research have focused more specifically on intervening at a younger age for children to promote early development (Kaiser and Hancock 2003).

A parallel literature has been devoted to interventions for children ASD where the parent is trained to deliver the intervention in lieu of a trained therapist. A plethora of single-subject publications demonstrate that parents of children with ASD can learn techniques for decreasing challenging behaviors as well as improving functional skills, features of autism, and overall compliance (Ducharme and Drain 2004; Lerman et al. 2006; Moes and Freas 2002; Smith et al. 2000; Symon 2005). Across the United States, comprehensive educational and intervention programs for children with ASD very often have a PT component as part of the package of services. However, only more recent years have PT in ASD have withstood the rigors of randomized controlled trials.

Rationale or Underlying Theory

Parent training programs have varied in the theoretical underpinning. The bulk of parent training programs have been behavioral in nature, either based primarily on operant conditioning or social learning theory. Much has been written about coercion theory and more recently on dynamic

systems principles as explanatory of the development of antisocial childhood behaviors (Granic and Patterson 2006). For parents of children with disruptive behaviors, but not ASD (non-ASD), there is a core assumption that deficit or dysfunctional parenting and parent-child interactions are at least contributory to the child's maladaptive behaviors. This hypothesis is not made for parents of children with ASD. Rather, the assumption is that parenting a child with ASD is particularly challenging given the child's core deficits, and parenting a child requires a higher level of skill and knowledge and higher level of input than that of developing a child without ASD.

PT programs specifically for ID and ASD have been primarily based on operant learning procedures but have also included developmental theory as well. The empirical support for operant learning procedures borne out of the field of applied behavior analysis (ABA) over the past 30 years is unequivocal for those with ID and ASD. These procedures have been in turn taught to parents. The rationale for including parents is based on several assumptions such as the child is most influenced by the parent, the parent spends considerable time with the child, and, of course, the parent is motivated, willing to learn and implement the behavioral procedures, and has the necessary resources to do so.

Goals and Objectives

While some PT programs for children with ASD have targeted disruptive, challenging behaviors (self-injury), other programs have specifically target core deficits to include communication skills, social skills, and adaptive skills. In keeping with a more stringent ABA model, PT for ASD has also focused more on determining the function of behaviors in children with communication deficits. In our own work, an emphasis has been placed on teaching parents to identify the function of their child's behavior. An emphasis has also been on teaching parents a range of antecedent management approaches such as the use of visual strategies and functional communication approaches as well as more traditional consequence approaches

(reinforcement, extinction, and mild punishments). Other PT programs have emphasized skill development related to core deficits and developmentally appropriate skills to include early prerequisite skills such as joint attention, imitation skills, non-verbal and verbal communication skills, and social engagement. More descriptive information of representative programs is offered in section G. PT has often been an adjunct to other interventions but has also been the sole treatment for children with ASD.

Treatment Participants

Within a PT model, both the parent/caregiver and child are considered participants. While the intervention is delivered to the parent, the primary outcomes of interest are those distal effects on the child. However, changes in parent behaviors are of interest as well. Parent variables associated with better versus poorer outcomes have been closely evaluated in the non-ASD literature, but are only now being evaluated more systematically in the PT literature specific to ASD. For PT for children with disruptive and noncompliance behaviors but typically developing, parent's adherence to the treatment has been shown to predict outcome, and specific attention to enhancing adherence has been studied (Nock and Ferriter 2005). Adherence has been defined in various ways but has included such variables as whether the parent regularly attended to sessions, parent completed requested homework, and parent implemented taught strategies.

While child variables associated with more or less response to PT have not specifically been determined in the ASD field, child variables more responsive to psychosocial treatments more broadly defined have been suggested. Higher developmental, cognitive, and language levels are believed to be associated with better outcomes in general and larger gains with psychosocial treatments. Not surprisingly, better outcome has been shown to be associated with fewer symptoms of ASD at outset. Much more research is necessary to determine which parent and which child with ASD will most likely benefit from a PT model of service delivery and then to

what PT program more specifically. Considerably more research efforts are needed before such questions can be answered.

Treatment Procedures

PT programs and procedures have widely differed across several variables. These include the intended target of PT program, the ages of the children with ASD included, duration or "dose" of training parents received, and how the program was delivered (individual, group, distant/online program). The PT may have been highly specific to the child or a manualized approach. Moreover, as already mentioned, the goals of the PT have been broad. For purposes of discussing the current literature, an overview of a few representative programs addressing challenging problems, those addressing core skill deficits and teaching of new skills, and finally those emerging programs via distant, Internet format are provided. It should be noted, however, that many programs overlap, particularly the more comprehensive, manualized PT programs. Table 1 provides more detailed information about these PT programs.

Programs Addressing Challenging Problem Behaviors

As already mentioned, research utilizing primarily single-subject designs has demonstrated parents of children with ASD can be taught ABA procedures and techniques to alter their children's targeted problem behaviors such as aggression, self-injury, noncompliance, and other disruptive behaviors. Much of this single-subject literature reported on teaching parents very specific, individualized ABA procedures to target one or two challenging behaviors. More comprehensive PT programs have taught parents and caregivers a range of ABA-based procedures (e.g., antecedent management, reinforcement contingencies, extinction, planned ignoring) to decrease their children's maladaptive behavior and teach new functional and adaptive skills. Two large-scale randomized control trials (RCTs) have provided evidence toward the efficacy of teaching a range of behavioral management

Parent Training, Table 1 Parent training programs

Reference	Participants N and age in months	Target behaviors	Dose of PT	Experimental design	Description
Smith et al. (2000)	N = 6 35–45 months	Children's receptive actions, nonverbal imitation, verbal imitation, and expressive object labels	Six (6 h) 1-day training workshops over 3 months	Multiple baseline across subjects	Taught parents to design and oversee a Lovaas-based discrete trial home-based program
Tonge et al. (2006)	N = 105 30–60 months	Parent mental health and adjustment	Twenty weeks of ten small group (90 min) sessions	RCT	Treatment groups Both manual-based PEBM: Parent education and behavioral management PEC: behavioral management and counseling
Solomon et al. (2008)	N = 19 60–144 months	Child problem and adaptive behaviors, parent stress, and shared positive affect	Two phases: six sessions each	RCT	Parent-Child Interaction Therapy includes two phases: (1) child-directed interaction and (2) parent-directed interaction
Anan et al. (2008)	N = 72 25–68 months	Child cognitive and adaptive functioning	Twelve weeks (180 h total/3 h each session)	Within single subject	Group Intensive Family Training: individual and group sessions with parent-child dyads Parents applied behavior analytic techniques in vivo with child. Staff modeling, coaching, and feedback provided
Whittingham et al. (2009)	N = 59 24–108 months	Parenting measures (i.e., laxness, overreactivity, verbosity, efficacy, satisfaction)	Nine sessions	RCT	Use of Stepping Stones Triple P in combination with ASD-specific interventions (comic strip conversations and social stories)
Nefdt et al. (2010)	N = 27 < 60 months	Parent elicited speech from child, parent confidence, treatment fidelity Child functional utterances		RCT	Self-directed learning model DVDs of PRT techniques
Kasari et al. (2010)	N = 38 21–36 months	Child joint attention, diversity of functional play	Twenty-four sessions, follow-up 1 year prior	RCT	Parent-mediated Joint engagement intervention, individual therapist-led sessions
Dawson et al. (2010)	N = 48 18–30 months	Child developmental levels and adaptive behaviors	Two years	RCT	Delivered by therapists and parents Combination of ABA, PRT, the Denver Model
Green et al. (2010)	N = 152 24–59 months	ASD severity rating Parent-child interaction, child language, adaptive functioning in school	Twice a week (2-h clinic sessions) and 6 months of booster sessions (total 18 sessions)	RCT	Preschool Autism Communication Trial: individualized therapist sessions to address social communication deficits

strategies to parents through a structured, manual-based approach. Sessions were individual and delivered through didactic teaching, use of videos, regular homework assignments, role-playing, and rehearsal with immediate feedback (Aman et al. 2009; Johnson et al. 2007).

A few other programs utilized a combination of individual and group sessions. Whittingham and colleagues (Whittingham et al. 2009) conducted a large study evaluating a PT model that incorporated ABA principles, social learning theory, coercion theory, and ASD-specific interventions (i.e., Social Stories™, Comic Strip Conversations™). This program extended an already established program (i.e., Stepping Stones Triple P) for parents of children with various developmental disabilities for use with parents of children with ASD. Training techniques (i.e., observation, practice, feedback) were employed throughout individual and group sessions to provide instruction in behavioral techniques (e.g., development of positive relationships, management of maladaptive behaviors, planning for high-risk situations, maintenance of behavioral changes). This method of instruction was shown to decrease problem behaviors and improve parenting skills (e.g., less overreactivity, verbosity).

Anan et al. (2008) reported on a program they called Group Intensive Family Training (GIFT). While the PT sessions were administered individually, these were followed by in vivo instruction of parent-child dyads in a group setting. In this case, staff taught parents to work with the other children also enrolled and to extend their use of behavioral principles by training an additional individual (i.e., spouse) to acquire the same skill set. GIFT not only decreased problem behaviors in young children with ASD but also significantly improved their cognitive and adaptive functioning.

Another group of investigators piloted the Parent-Child Interaction Therapy (PCIT) to children with ASD but who were higher functioning (Solomon et al. 2008). PCIT is a well-established, manualized parent training approach for children with early emerging conduct problems (Eyberg et al. 1995) and may hold promise for some parents of children with ASD. In this small pilot study, results reported improvements of parent

rating of child behaviors and improved “shared positive affect.”

Programs Focusing on Core Symptoms and Skill Acquisition

Parent training approaches to target improvements in the three core deficit areas (i.e., communication, social, atypical behaviors) of ASD diagnosis have received considerable research attention. These often include principles of ABA in combination of other theoretical approaches (e.g., developmental, transactional). Generally assumed in these programs is that in order to move children toward a typical developmental trajectory, parents should be taught specific skills to address core deficiencies in social, communication, and/or adaptive functioning. Representative programs are described below.

Smith et al. (2000) earlier investigated the use of group workshops as an effective mechanism to teach parents to design and oversee a Lovaas-based discrete trial home-based program, a commonly implemented treatment approach for this population. Children acquired new skills (i.e., receptive language, expressive language, nonverbal imitation, and verbal imitation) when parents served as therapists. However, the gains were not as substantial as made when the discrete trial therapy was delivered by a therapist.

Koegel and colleagues have developed and tested PT programs targeting what they describe as pivotal areas (i.e., motivation to engage in social communication, self-initiation, self-management, and response to multiple cues) (Schreibman and Koegel 2005). These key areas have been addressed through pivotal response training (PRT), an approach originally designed with a strong emphasis on parent-practitioner collaboration, and have been shown to be an effective intervention for all professionals (e.g., speech language pathologists, behavioral therapists, special educators) working with this population. PRT differs from more behaviorally based approaches due to its unstructured nature that capitalizes on the child’s motivation while embedding natural learning opportunities into daily activities. PRT parent programs have been shown to significantly improve communication and play skills but also a decrease in problem behaviors (Stahmer and Gist 2001).

Green et al. (2010) reported on a large multisite RCT investigation of a PT program called Preschool Autism Communication Trial (PACT). Therapist-guided individualized sessions taught parents to use communication responses and language appropriate for their children's developmental levels. Video feedback and a written summary of key session aims achieved were used to elicit discussion of parental acquisition of skills. Similar to PRT, PACT targeted core deficits in shared attention, form (e.g., nonverbal language, vocalizations) and function (e.g., request, gain attention) of language, and communicative intent. Although significant improvements in the parent-child interaction dynamic (i.e., child initiations, shared attention) were reported, a significant reduction in ASD symptoms was not found.

Other PT programs have focused on instructing and coaching parents how to teach imitation and joint attention given children with ASD do not learn these through typical parent-child interactions. The Early Start Denver Model (ESDM), a combination of PRT, ABA, and the original Denver Model, was reported on as a PT program to teach parents how to elicit critical behaviors (e.g., joint attention, imitation, attention) necessary for the development of functional, purposeful speech in their children. This manualized program includes a PT component along with a therapist-delivered intervention component. In a large RCT, program was shown to improve the child's skills toward a more typical developmental trajectory (Dawson et al. 2010). Similarly, Kasari and colleagues reported on what was described as a parent-mediated intervention to improve joint engagement in a sample of toddlers (Kasari et al. 2010).

Parent Training Programs That Promote Training for Distance Learners

As the prevalence of ASD escalates, so does the need for feasible, accessible training for caregivers living in areas where services for children with ASD are not readily available. The delivery of PT through distance-based telepractice (e.g., video training, phone consultation) has been shown to be a possible alternative to clinic-based

practice. A recent RCT examined self-directed learning through a structured PRT curriculum delivered sequentially through DVD instruction in the home environment. Functional speech and parental confidence in treatment implementation were noted as positive outcome measures in this case (Nefdt et al. 2010). Other programs have been developed but have yet to report on effectiveness. A couple examples can be viewed at www.autismacademy.com and www.simplestepsautism.com.

Efficacy Information

PT as an efficacious intervention depends on the criteria used to define efficacy. While the ABA single-subject literature offers strong support for the use of PT as an intervention for children with ASD, only a few studies have used randomized controlled or controlled trials. Hence, in a systematic review, McConachie and Diggle (2007) concluded that further research is needed and suggested future studies should include adequate sample sizes, use standardized outcome measures, as well as attention to the components of the training. There is an urgent need for more large-scale RCTs using assembled manuals to more fully evaluated PT as well as other behavioral and psychosocial interventions (Smith et al. 2007). However, the need for effective intervention for children with ASD is now. At the time of writing, several other large-scale PT studies are under way and hopefully will begin to fill the gaps in our knowledge.

Outcome Measurement

Measure of outcome in the field of ASD has been fraught with many challenges. For psychosocial interventions, the choice of outcomes is complicated by the frequent multiple or less than exact goals of the intervention, the heterogeneity of children with ASD, the feasibility of completing direct measures with often uncooperative children with ASD, and the desire to have measures blind to the participants and/or investigators (single- or

double-blind studies). In the single-subject literature, the outcome measures have often been highly specific, operationally defined directly observed behaviors (e.g., frequency of use of joint attention, frequency of aggressive behavior, percent compliance). Direct observation methodology has often been used in some larger RCT PT programs. Parent and child are videotaped for later coding of both child and parent behaviors (e.g., Johnson et al. 2009; Kasari et al. 2010).

Broader outcomes incorporated have been behavior rating scale of behaviors completed by an informant (i.e., parent/caregiver, teacher) when the PT is primarily targeting behavior problems. In one large RCT, the Aberrant Behavior Checklist (Aman et al. 1985) was used, given it had previously been shown to be sensitive to treatment change. Global ratings completed by an independent evaluator who is naïve to intervention arm have been suggested as a measure. The Clinical Global Impression Scale (Guy 1976) was used successfully in the RUPP-PI Autism Study (Aman et al. 2009). Measures to assess the presence of core features over time have also been included in a number of PT studies. These have included the Autism Diagnostic Observation Schedule (Lord et al. 2002) and the Autism Diagnostic Interview-Revised (Lord et al. 1994). A wide range of developmental, cognitive, language, and adaptive behavior measures have also been included as outcome instruments. A few examples include the Mullen Scales of Early Learning (Mullen 1995), the MacArthur CDI (Fenson et al. 1993), and the Vineland Adaptive Behavior Scales (Sparrow et al. 2005).

Measures of parent well-being and satisfaction have often been included as outcomes in PT programs. The Parenting Stress Index (Abidin 1995) is a frequently reported parent outcome. Program-specific parent satisfaction measures are often employed as well.

Qualifications of Treatment Providers

The background and training of those providing the parent training have varied in what has been reported in the literature. For those providing

parent training steeped in ABA, a working understanding of these concepts and how they apply to procedures and strategies for children with ASD is essential. While it is imperative to have this conceptual and technical knowledge base, it is also essential that PT providers have the additional therapeutic skills to establish working alliances with parents/caregivers and are able to motivate parents toward change. Hence, PT providers require the therapeutic skills essential for other more traditional therapies. Others have more explicitly described important skills in those providing parent training such as a collaborative style with the parent, ability to provide immediate feedback, and ability to individualize interventions even if the treatment delivered is within a manualized program (Kaiser and Hancock 2003). All in all, an effective PT provider is also an effective clinician in general.

Parental Action and Referral Patterns in Spatial Clusters of Childhood Autism Spectrum Disorders

David Schelly

Disparities in ASD diagnosis

Definition

Spatial clusters of ASD cases were first identified in California, where children born in certain geographic areas had a substantially higher “risk” of diagnosis (i.e., higher per capita rates of ASD) compared to children born elsewhere (Mazumdar et al. 2010). For young children, Liu et al. (2010) even found that the risk of diagnosis increased when their families moved to within closer proximity to already-diagnosed children. Having ruled out environmental causes, the authors hypothesized that “information diffusion” was the cause – essentially, parents of some children were more likely to seek professional medical help if they were exposed to information about ASD (see Fountain et al. 2011). One possibility was that mothers were meeting and talking about their children’s development while they exercised at the mall and waited for their kids at school (e.g., Liu and Bearman 2015).

An alternative to the parental help-seeking hypothesis is that geographic disparities in ASD diagnosis are simply a consequence of physician referral patterns (e.g., Emerson et al. 2016). Kalkbrenner et al. (2011), for example, found that living in close proximity to neurologists and psychiatrists was a good predictor of diagnosis, and it is reasonable to assume that some primary care physicians are more likely than others to refer borderline cases to diagnosing specialists. In Denmark, Lauritsen et al. (2014) found that the risk of diagnosis increased when children’s families moved to more urban areas, where diagnostic services were more readily available.

Because these hypotheses are difficult to test in settings with decentralized diagnosis (e.g., diagnosing physicians everywhere) and extreme variation in access to medical care, Schelly and his colleagues considered the case of Costa Rica. Children in Costa Rica have universal healthcare, and there is one centralized diagnosing clinic. Schelly et al. (2015) started by identifying spatial clusters of ASD that exhibited similar characteristics as those in California (e.g., high socioeconomic status) and elsewhere (e.g., high urbanicity). Next, the authors interviewed parents of diagnosed children to determine what

information they had been exposed to, and what children with ASD they knew, leading to the diagnosis (Schelly et al. 2018). There was little evidence that parents were influencing each other; rather, higher socioeconomic status parents were able to avoid delays in the public healthcare system by paying out of pocket for private specialist care, increasing the likelihood of being referred directly to the diagnosing clinic. Schelly et al. (2019) outline barriers to an information effect that likely also apply in other settings: early symptoms of ASD are often generic, giving parents no reason to suspect ASD in particular, and parents are almost universally aware of early problems and seek medical care for them long before there are opportunities at the mall or in school for other parents to influence them; furthermore, because children with ASD can appear so different – one will stare at walls and another will throw tantrums – knowing a child with ASD may only help in rare cases when the child in question happens to have similar behaviors as one's own.

For now, physician referral behaviors appear to have a stronger influence than parental help seeking behaviors on spatial clusters of childhood ASD, but both mechanisms likely play a role. One solution, though, would alleviate diagnostic disparities no matter the cause: provide better healthcare for all children, and make it easier for all families to access specialist care.

Parental Attitudes to Technology Use

Margaret Holmes Laurie

Centre for Clinical Brain Sciences, University of Edinburgh, Edinburgh, UK

Definition

This entry will focus on the attitudes and concerns of parents and caregivers about their autistic child's use of technology. The role of digital

technologies in the lives of children and young people has become a popular debate in recent years, with concerns about the impact of increased media use on a range of developmental domains, including social interaction (Bell et al. 2015). In this entry, the focus will be on technology used by autistic children and young people for leisurely purposes in home environments.

Historical Background

Technology and related topics are recognized as a common interest within the autistic population, and technological skills and affinities are a common stereotype made about autistic people. Baron-Cohen and Wheelwright (1999) asked 92 parents of children with autism about their child's special interests, and 64.1% of them reported that their child had an interest in television or audio media. A more recent survey of 687 autistic adults showed that after autism, computers and gaming were the most popular special interest topics, and especially popular among autistic men (Grove et al. 2018).

Technology develops at such a fast rate that research about the use of technology is quickly outdated, as new devices proliferate the consumer market. For instance, reports which predate the launch of mobile touch screen devices, such as tablet computers and smartphones (e.g., Shane and Albert (2008)), cannot provide insight into current uses of digital media. And likewise, reports which focus on only one device, such as the Apple iPad® (e.g., Clark et al. (2015)), tell us little about what the impact of having multiple devices within households has on parental attitudes to technology and child development.

The term “technology” nowadays refers to a broad range of devices, including different interfaces (screen, touch screen, handheld, robotic), different software (including different types of content, apps), and different contexts of use. By contexts of use, I mean, for example, that in a given morning, we might use our smartphone to check the weather forecast, purchase a bus ticket, listen to music, check emails, pay for a coffee, and text a friend, all before arriving to work for the day. A child might also use a computer “or tablet”

to watch a cartoon, do homework, play a video game, or do their own research about a specific topic. All of these activities and contexts are pulled together when considering “technology use” more broadly, which greatly limits conclusions drawn from sweeping generalisations about technology use.

Current Knowledge

A range of technologies play an important role in the lives of autistic children and young people and are a common reported leisure activity at home (Laurie et al. 2018). The concerns that families report about their autistic child's technology use will be discussed in three domains: screen time, social interaction, and online safety. Screen time concerns are closely related to the repetitive behaviors domain of autism, where parents are concerned about the amount of time that children spend using technology. Concerns about the impact of technologies on social interaction relate to the social differences often observed with autistic children, with the assumption that technology will increase or exacerbate social difficulties over time.

Screen Time

Then time that children spend using digital devices is a highly reported concern, among parents of autistic and non-autistic children alike. Parental concern about the time that autistic children spend using digital media and devices has been shown in a number of reports (Laurie et al. 2018; Mazurek et al. 2012; Mazurek and Wenstrup 2013). Whether autistic children spend more time using technology than non-autistic children is a hotly debated question and has been suggested in some studies which compare the use of technology by autistic teenagers with their non-autistic siblings (Mazurek and Wenstrup 2013). However, a large-scale study which included data from over 65,000 children did not find evidence that screen time in autistic children (aged between 6 and 17 years of age) differed from screen time in non-autistic children (Montes 2016).

Nonetheless, the amount of time that autistic children spend using digital technology at an

individual level is still of concern to parents and families. A majority of parents report using strategies to limit their autistic child's use of technology, including using timetables, timers, and letting children access technology after they have done a certain task, such as homework (Engelhardt and Mazurek 2014). One possible reason is the displacement hypothesis – the prediction that time spent online or using technology is replacing time spent doing other activities, which are presumably healthier, more beneficial, or more productive than technology use. One example of such a concern is that time spent on screens is replacing the time that children spend engaged in outdoor or active play, thus increasing the risk of obesity through sedentary behavior (Must et al. 2014). However, other studies report that autistic children engage in a mixture of both digital and outdoor play (Shane and Albert 2008), therefore suggesting that time spent using digital devices is not replacing time spent on other activities.

Technology and Social Interaction

The social displacement hypothesis also predicts that the more time people spend on the Internet, the less time they spend engaging in face-to-face interactions. Autism is associated with differences in social interest and motivation, which can lead to a preference for solitary activities, such as those traditionally offered through the use of technology (Mazurek and Wenstrup 2013). However, a number of reports have demonstrated the role of seemingly “non-social” technology use in the lives of autistic children. Technology can provide important cultural knowledge for children to connect with their peers, including shared interests in video games or television programs (Fletcher-Watson and Durkin 2015).

One question is whether autistic people's use of technology displaces social interaction in the real world. The “rich get richer” hypothesis predicts that those who are socially popular in offline contexts will use online-mediated communications to enhance their already-existing social relationships and thus benefit more from online communications. Meanwhile, the “social compensation” hypothesis predicts that those who are more introverted or have fewer social relationships will seek out online interactions and therefore benefit

from social connectedness with others as mediated by technology. Early studies supported the rich get richer hypothesis by reporting that autistic teenagers were less likely to use technology for social purposes, including the use of social media (Mazurek and Wenstrup 2013). However, more recent studies have reported that autistic people are active on social media platforms and reportedly prefer to socialize with others over online platforms (Gillespie-Lynch et al. 2014).

Online Safety

The online safety of autistic children is a concern to many parents, particularly of older children who are active Internet users. Just and Berg (2017) report on a series of workshops with parents of autistic children, to identify major concerns that they had about their autistic child's online safety. The concerns that were raised in the workshop included spending money online (e.g., downloading apps, loot boxes, etc.), awareness and understanding online interactions, and accessing inappropriate online material. Some parents reported that their children's motivation to play online games resulted in high amounts of, and sometimes illicit, online transactions. One parent noted that their child was so computer-literate that they could divert any blocks and restrictions put on the account or device and would memorize passwords to access payment details. Another concern reported by parents was their child's social vulnerability transferring into online contexts. Some parents shared that their child had been bullied online, and others said that their child had difficulty managing online risks in relation to social or identifiable information. For instance, some children had no awareness of social privacy and had difficulty recognizing online interactions that were inappropriate (Just and Berg 2017).

Future Directions

Much research has investigated how technology can provide educational and therapeutic benefit for autistic people (Bölte et al. 2010). Increasingly, research is starting to look at the broader role that technology plays in the lives of autistic

people, including the potential opportunities for social connectedness and well-being via use of technology (Stiller et al. 2019). However, parents have also raised a number of concerns about their autistic children's technology use, and research should be responsive to those concerns. This includes evaluating technologies which autistic people are regularly using and focusing on areas of concern for families, including the impact of technology on children's attention, behavior, learning, and interaction.

One challenge for researchers is keeping up to date with the latest digital innovations. On the one hand, research is quickly outdated by technical development, and so research on newly released or up and coming devices is warranted, such as the study of virtual reality and robotics (Good et al. 2016). However, families and caregivers will only benefit at present from evidence on the devices that they are currently using. Parents seldom reported that their autistic child used apps and technologies specifically designed for autistic people and instead the most common types of devices used in the family home were mainstream commercial products (Laurie et al. 2018). There needs to be a balance between preparing for the digital future and also being responsive to current concerns about technology use. One potential solution is research collaborations with individuals and families, to devise and share strategies for managing their concerns about technology. One example of this is the guidelines offered by the National Autistic Society in the UK, based on research and interviews with parents about their autistic child's technology use. Here, the National Autistic Society offers guidance for parents in choosing specific devices for their child and managing their child's use of technology and encourages parents to think about the benefits of technology use for their child (National Autistic Society 2015).

One potential research solution is to identify the digital contexts or features which lead to certain outcomes for autistic people, rather than studying technology at the level of specific devices or apps. This would allow for more general statements about features and contexts, which could be translated across multiple

devices or software, such as screen-based technologies, or apps with this type of interactive mechanism (Fletcher-Watson 2015). For instance, identifying what is it about online games that are appealing to autistic children or moments of technology use where children specifically choose or don't choose to interact with others (Laurie et al. 2019). By identifying the contexts and motivations for autistic people to use technology, better theories can be proposed to explain autism and digital affinity (Laurie et al. 2018). For instance, current theories about digital affinity relate to technical features of technology suiting the learning style for autistic people, e.g., visually presented, predictability, and replicability of digital content (Rajendran 2013; Stiller et al. 2019). Firsthand perspectives from autistic people could provide further insight toward the development of theory in this area. These perspectives could also encourage parents of younger autistic children to think more positively about their child's use of technology or identify ways in which they could support their child to stay safe online.

One final suggestion for future research is to improve representation of non-verbal autistic people, people with learning or physical disabilities, and younger children. Parents of children and young people within these demographics may have different concerns or views about technology use. However, reports of parental concerns are not without their limitations. Parental perspectives are often used in proxy to gather information about technology use from particular groups, such as young children or those with learning disability (Laurie et al. 2018; Mazurek and Wenstrup 2013). Parents' reports of their child's technology use are influenced by their own attitudes about their child's use of digital devices. For instance, parents who reported more concerns about their child's screen time were more likely to report that their child spent more time using technology (Laurie et al. 2018). And when recruiting for research about technology, it is hard to achieve true representation, since those with more extreme (positive or negative) views are more likely to be vocal or responsive to research calls.

Parental Caregivers of Adults with Autism

Christina N. Marsack-Topolewski
College of Health and Human Services, Eastern
Michigan University, Ypsilanti, MI, USA

Definition

A caregiver is a person who provides physical, emotional, social, and financial care or support for another person who is physically, cognitively, or emotionally challenged; has a disability including autism; or a chronic/serious illness that impacts his/her ability to function independently. Caregiving can be temporary or long-term depending on the condition and needs of the individual requiring care. Autism spectrum disorder (ASD) is a continuum that ranges from very mild to very severe, generally is diagnosed in early childhood, and requires reliance on caregivers to help meet daily needs. Caregiving for individuals with ASD typically is provided by parents and begins early in life and continues throughout adulthood. As individuals with ASD age and move into adulthood, they often continue to rely on their parents for care. Parents often provide care until they are no longer able and then caregiving generally falls to siblings, other family members, or close friends. In some cases, the adult with ASD may require formal caregiving either in group homes or through shared living arrangements.

Current Knowledge

During the past two decades, the prevalence of autism spectrum disorder (ASD) has become

a national concern, with the percentage of individuals diagnosed with this condition increasing by 269% (Van Naarden Braun et al. 2015). ASD is a developmental disability that is characterized by impairments in communication and social interaction, as well as restrictive, repetitive behavior (Autism Speaks 2016). Although most individuals with ASD are diagnosed at a young age, they do not outgrow the condition and continue to exhibit symptomology across the lifespan. While the typical belief is that ASD is primarily a childhood condition, an estimated 6.6 million individuals (5.3 million adults and 1.3 million children and adolescents) worldwide have been diagnosed with ASD (Nightingale 2012). Even as adults, individuals with this condition experience a range of impairments that impact functioning with regard to social, communication, and behavioral atypicalities (DaWalt et al. 2017; Leung et al. 2018).

Research on ASD generally has focused on children and their parents, while adults with ASD and their parental caregivers have not been studied to the same extent (Wright et al. 2013). As individuals with ASD transition from childhood to adulthood, the manifestations of their conditions, while changing, can be expected to continue throughout their lives. Many children with ASD have comorbid conditions that can cause greater challenges for caregiving. For example, many children with ASD also have intellectual deficits and mental health issues that complicate the caregiving process (Brondino et al. 2019; Hudson et al. 2019). These comorbid conditions do not go away, but extend across the lifespan.

Many parents can expect to continue to serve as caregivers, varying to some degree, depending on the extent of their adult child's ability to function independently. Caregiving can be burdensome, requiring parents to forego normal aging milestones and causing them to become advocates for obtaining social support services for their adult child with ASD (Marsack and Perry 2018). Understanding their challenges related to realities of caregiving and overall quality of life (QOL) is important as they continue to support their adult children with ASD.

Realities of Caregiving

Caregiving is ongoing and relentless because ASD continues across the lifespan and can pose intergenerational consequences for family members. Regardless of how the caregiver feels, she/he must provide care for their adult child with ASD. They often assist with activities of daily living that could include bathing, feeding, managing atypical behaviors, and helping with money matters. Parents rarely get time off to rest and reflect because they have few people (paid or unpaid) in their lives on whom they can depend to provide the care their adult child needs. Caregiving can feel thankless and exhausting, with many parents overwhelmed by the constantness of caregiving and lack of respite from their responsibilities (Oti-Boadi et al. 2019).

The term “panini sandwich generation” has been used to refer to parents who are caring for multiple generations at the same time (Abramson 2015). As discussed by Marsack and Hopp (2018), some parental caregivers may be responsible for caring for their aging parents, other children with typical and atypical development, spouses as they age, as well as other family members with chronic conditions (e.g., dementia, schizophrenia, or intellectual/developmental disabilities). Caregivers providing care for adults with ASD and other loved ones with varying levels of need may feel particularly “pressed,” while they navigate their own personal and work-related responsibilities.

Caring for an adult child with ASD can result in parents’ loss of identity and inability to have lifetime experiences similar to their same age peers. Parents providing care to an adult with ASD may become isolated from their normally aging friends because they lack time to socialize or find a responsible caregiver (either paid or unpaid) to stay with their adult child for extended periods of time. They are aware that their adult children with ASD may never marry, have children, or live independently. Caregiving becomes burdensome when parents perceive they are missing out on the normal life stages and have to subsume their goals constantly to meet the needs of their adult children with ASD or other family members requiring their attention.

Caregiver Burden

Caregivers’ perceptions of stress and fatigue resulting from ongoing efforts needed to provide physical and emotional support for individuals with conditions that require special care. Four types of caregiver burden, time dependence, financial, developmental, and emotional burdens, often associated with caring for an adult with ASD have been identified in the literature (Novak and Guest 1989). Time required to provide care for an adult with ASD is considered time dependence burden. Parents often postpone or forego participation in personal activities to meet the demands of their adult with ASD (Marsack and Perry 2018). Parents of adults with ASD can expect to experience financial burden due to the costs associated with informal and formal support, as well as lost wages while caregiving (Rogge and Janssen 2019). Developmental burden occurs when the parents of an adult with ASD recognize that their lives are incongruent with peers who have adult children without disabilities (De Fazio et al. 2015). Caregiving can result in emotional burden for parents of adults with ASD, including psychological distress and impacts on psychological health (Herrema et al. 2017; Keenan et al. 2016; Marsack and Samuel 2017). Caregiver burden, regardless of the type, experienced by parental caregivers can have a negative effect on QOL.

Quality of Life

Quality of life is defined by the World Health Organization (WHO) as “individuals’ perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns” (WHO 1996, p. 1). QOL is a multifaceted construct comprised of six components: (a) social, (b) physical, (c) psychological, (d) spiritual, (e) cognitive, and (f) environmental well-being (Kelley-Gillespie 2009; Salvador et al. 2014). Each of these components is associated with caregiver burden that parents of adults diagnosed with ASD experience. Individuals self-assess the quality of the interactions between personal and environmental factors to determine their QOL. If parents of adult children perceived less emotional burden (i.e., stress and depression

in their lives), their QOL was likely to be higher. Yoong and Koritsas (2012) used a sample of older parental caregivers of adults with developmental disabilities to study the association between caregiver burden and QOL, based on the WHO definition of QOL. Time needed to provide care for their adult children had a negative effect on parents' participation in leisure activities that impacted their QOL (Yoong and Koritsas 2012).

Informal Social Support

A negative relationship exists between caregiver burden and QOL for parental caregivers who have an informal social support network that helps provide care for the adult child with ASD (Marsack 2016). Informal social support networks generally are comprised of family and friends who provide emotional and physical support in caring for an adult with ASD. For example, a family member could spend an afternoon with the adult with ASD to allow the caregiver to shop, see a physician, or just rest. While parental caregivers continue to age, many will experience a shrinking informal social support network due to death or other naturally occurring reasons (Carstensen 1991). However, these results demonstrate particular vulnerabilities for small, diminishing, or absent informal social support networks or circles. Given the propensity for older adults to experience shrinking networks, it is particularly important to be aware of this tendency.

Formal Social Support

In addition to informal social support, caregivers and adults with ASD may be able to access social support services through formal networks available from government, nonprofit organizations, or community agencies (Roux et al. 2017). Parental caregivers face a myriad of challenges when attempting to coordinate and navigate services as their adult children with ASD transition from adolescence to adulthood (Anderson et al. 2018). While children receive many formal supports through the public education systems in their states at no cost, many of these services have costs associated with them, adding to the financial burden of providing care for adults with ASD (Anderson and Butt 2018; Müller and Cannon

2016). For approximately 25% of parental caregivers, services that could have helped their adult children with ASD were unavailable in their areas, with another 26% unaware of services that could benefit their adult child (Dudley et al. 2019). However, variations in service availability often are based on location (e.g., state-to-state, within-state, rural vs. suburban; Marsack and Perry 2018), with some parents choosing to move to obtain better services for their adult with ASD. Fighting for services and working through bureaucratic systems that were challenging and complex could prove to be too much for some parental caregivers. The inconsistency of some formal supports could be problematic for parents because of high employee turnover, inadequate training, negative attitudes, as well as subpar wages that exist among direct care workers and professional staff. Because of dissatisfaction with, or unavailability of support programs, some parents of adults with ASD used their own resources to develop specialized activities or personally hire and pay staff.

Rewards

Although being a parent of an adult with ASD has been associated with challenges and stressors that add to caregiver burden, many parents also reflect on the rewards resulting from seeing their child make changes, however, small. In recognizing these changes, many parents reported increased spirituality and faith (Pakenham et al. 2004). They have developed greater patience and compassion for others in the community who are experiencing similar caregiving issues. Some parents become active in the community, advocating for greater awareness and improved services for both their adult children, as well as for other parents who are caregiving for adults with developmental disabilities. Some parents consider the reciprocity in care between parents and their adult children with ASD as a reward that reduces the stress associated with caregiving. Both emotional and tangible benefits can emerge from the relationship between the parent and adult child dyad (Perkins and Haley 2010, 2013; Williams and Robinson 2001). Rewards from parenting an adult with ASD can serve as a buffer to reduce stress associated with caregiver burden.

Planning for the Future

In addition to helping their child with ASD become as successful as possible as they become adults, parents also have to consider future and potential plans that will be needed to accommodate their own aging, as well as their adult child's changing needs. Making future plans differs among parents relative to the severity of ASD, family composition, and financial stability. For example, some parents of adults with ASD may have other children who are willing to assume caregiving, while other families may have little or no familial support on which they can rely. Minimal planning by parents is needed if their adult child is high functioning, with more extensive plans required for adult children with ASD who are more impaired or have multiple conditions.

Although parents understand that making plans for the future is necessary, they may struggle with finding a person who is willing to assume responsibilities associated with caring for an adult with ASD at the same level as the parent (Oti-Boadi et al. 2019). Parents may be reticent regarding future planning because they have been busy with today's problems and have not taken the time to consider the need for a comprehensive plan for their adult child's caregiving needs (Bowey and McGlaughlin 2007; Mansell and Wilson 2010).

Most parents are aware that, as they age, providing care for their adult with ASD will become more stressful (Grossman and Webb 2016). They worry about who will provide care for their adult child when they are unable to meet the demands associated with caregiving. In a study by Marsack-Topolewski and Graves (2019), aging parents of adult children with ASD shared a number of future-oriented concerns, including (a) difficulty identifying caregiving support for the future, (b) barriers to making plans/decisions, (c) fear of the unknown, and (d) feeling the need to make plans and decisions now. Many aging parents feel that a new caregiver will encounter difficulties when attempting to navigate the service system for their adult children with ASD, causing concerns that their child will not receive services needed for daily life.

Future Directions

In the upcoming decades, the number of individuals diagnosed with ASD reaching adulthood is anticipated to increase, along with the number of parental caregivers who can expect to continue providing some level of support to their adult children (Gerhardt and Lainer 2011). While these parents have reported many rewards associated with having an adult child with ASD, these parents also face challenges as they continue to age. To diminish effects of caregiver burden, professionals working with parents can help them join or form informal social support groups with others who have an adult child with a disability (Marsack and Church 2019). Practitioners need to understand the complexity associated with caring for an adult with ASD and the needs that change over time, as well as the complexity of family dynamics that effect caregiving.

Maintaining a balance between providing care for the adult child and caring for themselves can become difficult as parents age (Hines et al. 2014). Caregivers need to be encouraged to start making future plans for their adult child, including finding guardians who are willing to assume responsibility for caregiving. At the same time, future planning should provide help for parents as they experience age-related decline. Professionals, such as social workers, case managers, and health professionals, need to help parents develop contingency plans for when they are unable to provide care for their adult with ASD.

Introduction

Autism spectrum disorders (ASD) are a range of neurodevelopmental disorders classified in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-V) (American Psychiatric Association 2013) to encompass autistic disorder, Asperger's syndrome, childhood disintegrative disorder, and Pervasive Developmental Disorder-Not Otherwise Specified (PDD-NOS) (American Psychiatric Association 2000). The disorders have a life-long expectancy and demand for care and treatment, both from parents and professionals. In most Western cultures, children with ASD attend school during daytime, either regular schools with adaptation or specialized schools. Some individuals also do have structured intervention programs implemented at home.

Even if these individuals spend a great amount of time together with professionals, e.g., teachers or other caregivers, parents are spending most time and are thereby considered as the primary caregiver for the individual. The consequences are that parents often experience and bear a great deal of responsibility and care (Volkmar et al. 2014). It should be noted that an ASD diagnosis does not only affect parents but also to a great extent siblings and other close relatives. Lovaas et al. (1973) stated that collaboration between parents and professionals, such as teachers or behavior analysts, is beneficial to the outcome of structured intervention programs. However, this collaboration can be difficult to establish and preserve, often because parents have different prerequisites, and not all parents have financial or nonfinancial resources, which would allow such collaboration.

Parents often start worrying when the child does not make the same milestones as other children, and referral to a specialized clinic is often based upon the concerns parents have when their child shows delay in development of speech and motor skills. Other concerns are often related to stereotypic and/or repetitive behavior (Volkmar et al. 2014). The process of receiving a diagnosis is often a troublesome one, mostly because parents tend to hope that the child will grow out from the delay but also because of long referral time to specialized clinics (Volkmar et al. 2014). Obviously this period can be demanding for parents, due to the amount of concern they encounter and especially due to the waiting time for a clinical assessment.

Post-Diagnosis Emotions

Each parent of a recently ASD-diagnosed child will experience this period in their own unique way; however there are similarities. Previous studies have shown that parents with a recently diagnosed child have elevated levels of depression and even post-traumatic stress disorder (Dabrowska and Pisula 2010; Casey et al. 2012). Others experience a sorrow process including denial, grief, anger, and acceptance (Lutz et al. 2012), while others have a hard time coping with everyday life which often is

experienced as being in “a vacuum,” not knowing what to do. Emotional stress is just one of the consequences parents experience. Mothers, in particular, have an elevated level of emotional stress and depression (Volkmar et al. 2014). One factor that might explain this is that mothers more often take on the role as primary caregiver (Volkmar et al. 2014) and give up their professional career than fathers. There is also a common feeling of disappointment among the parents, not over the child, but over the fact that they are not going to experience all the normal milestones and experiences of a typically developed child (Lutz et al. 2012; Schwartz 2001). As the child grows up and turns into adolescence and young adulthood, a very common concern among parents of individuals with ASD rises, related to the future quality of life of the child if the parents either could not provide the necessary care anymore or if they would pass away (Schwartz 2001; Kalash 2009). The concern is often related to a concern whether or not the child will receive necessary care and support and how this will affect their child’s quality of life.

It is important to address the emotional stress a parent is experiencing when their child is diagnosed with ASD and the related ruminations concerning their child’s future. On the other side, one may not forget the positive sides of being a parent, no matter if your child receives an ASD diagnosis or of another developmental disorder. Parents of children with ASD can also experience a positive effect onto personality and by advocating for their child (Scorgie and Sobsey 2000). Pakenham et al. (2005) described the ASD diagnosis also as exerting a possible positive effect on patience, tolerance, and empathy. From recent studies it emerged that parents of children with ASD also tend to have a great property in caring, sharing, and enjoying the smaller things in life, such as returning a wink or a kiss (Lutz et al. 2012). Many of the parents prefer to speak about their children’s strengths rather than the consequences of the diagnosis, by advocating heavily their personality and interests. Sometimes parents become even motivated by their child to take a degree on the disorder, and some end up as clinicians and researchers. Having a child with an autism spectrum disorder will in most cases

involve heavy workloads, little sleep, and concern for both the present and the future. However, it is also important that parents, clinicians, social workers, and other professionals address the positive sides and encourage parents to enjoy the bright spots and the achievements the child is accomplishing. Having a child with autism can definitely imply joy for the parents.

Reactions to Choice of Treatment and Services

Parents often experience the decision-making process around treatment and services for their child as stressful. Often they feel overstressed when facing all the different treatment and intervention options, which make them feeling unsure about which one is the optimal for their child (Ewart 2002). The different services are provided depending on the location (countries, states, counties, and cities). In addition, there are different procedures on how to obtain these services. Most children with ASD in the United States and other developed countries attend schools with professionals where they get familiar with the staff. However, services such as respite services are in many cases not used, because of the emotional stress the child is experiencing when spending time with a less familiar person. Other parents report that the information from service providers often are lacking, giving a feeling of hopelessness (Kalash 2009). Ewart (2002) regarded obtaining school services and rights as difficult. An example from Norway is that many parents are not familiar with the wide range of services they as a family are entitled to, leaving many with negative attitudes toward specialized clinics and state-funded organizations.

Everyday Life Aspects

As mentioned there are often emotional stress-provoking challenges parents of children with ASD are encountering in terms of adaptation, family life, and also stigmatization when in public with their child. It is also time consuming to

follow up on what the child might have experienced at school, causing parents to customize their life and that of other family members (Lutz et al. 2012). For many parents, it is a struggle just to go to the store with their child, not necessarily because of the child's behavior, but more often because of the stigma felt from other adults (Schwartz 2001). Each parent having a child with ASD will remember the different looks people are throwing (Hunt-Jackson 2007). This can be offending and hurtful situation for parents, making them feel embarrassed, pitiful, or even as if they were bad parents. Many parents experience that the more subtle the public reactions are, the more judgmental they are concerning their child's behavior (Neely-Barnes et al. 2011).

Spousal Relationship

Previous studies indicated that parents of children with ASD had a high rate of divorces. However, more recent studies have shown that despite an increased number of marital conflicts and stress (Benson and Kersh 2011), the divorce rate is much lower than initially found (20 % divorce rate reported by Hartley et al. 2010). Parents often refer to the difficulties of balancing marital needs and the needs of their child. It seems especially hard to combine a marital need with the adjustments and the considerations they have to take concerning their child (Schwartz 2001). Parents also often have problems with maintaining their social network after such a diagnosis (Volkmar et al. 2014). For many it can be rather sore to be around friends with typically developed children, which can cause a marital stress. However, coping with social situations can also strengthen the spousal relationship, which is reflected by many reports about spouses being regarded as the most important support person (Volkmar et al. 2014).

Summary

It is clear that parents of children with ASD experience numerous challenges both as individuals and as couples. Many find the immediate time

after a diagnosis as both emotionally stressful and a grief process comparable to individuals mourning the loss of a close family member. When parents get familiar with their child's diagnosis, there are often positive effects to be observed, such as personal growth and becoming supercharged in advocating both their child in particular and in some cases autism spectrum disorders, in general. Spousal relationships have also been studied, without finding an increased risk of separation or divorce compared to parents of typically developed children. Many parents also regard that they find their spouse as their closest supporter, even if there is an increased marital stress in these marriages.

From the different studies referred to in this chapter, it can be concluded that information about treatment and services should be systemized in a better way, to relieve parents from some of the stress they experience during the time of diagnosis and beyond. Support groups for parents are also a very powerful tool for their marriage, and an increased focus on marital difficulties and issues is warranted. In general, there are challenges and consequences of having a child with ASD, which can be difficult to handle for many individuals. The demands parents are experiencing both concerning to sustain a healthy spousal relationship and a well-functioning family situation often require everyday life to be planned and rigorous. It is therefore important that clinicians, social workers, and other professionals manage to provide parents of a recently diagnosed child with information on both the challenges and possibilities arising in the wake of this event.

Parent-Implemented Bedtime Fading and Positive Routines

Katerina Dounavi and Emma Delemere
School of Social Sciences, Education and Social
Work, Queen's University Belfast,
Belfast, UK

Definition

Stimulus control is the principle underlying the most common behavioral interventions targeting sleep habits, such as positive routines and bedtime fading. Stimulus control posits that falling asleep is the final step of a behavior chain, in which initial steps are pre-bed behaviors that lead to a state of calmness.

Positive routines are defined as a series of five to seven calming activities that move from active to passive and are undertaken during wakefulness to facilitate quietude and sleep onset. When establishing positive routines, completion of each step in the routine is met by praise, notifying the individual of the transition to the next step.

Bedtime fading is defined as a sleep intervention in which bedtime is moved to match an individual's natural sleep onset time and increase the likelihood of quick sleep onset. Bedtime is then systematically altered over time to more closely approximate developmental norms and family habits.

Historical Background

Good quality sleep is vital for health and overall well-being. Sleep disorders affect 25–40% of children (Owens 2007), most of whom will continue to face sleep difficulties throughout their lifetime if untreated (Mazurek et al. 2019).

Poor sleep negatively impacts on cognitive function, health, behavior, and well-being (Abel et al. 2018). Although quite prevalent in the general population, sleep disorder rates double among

those with developmental disorders, such as autism spectrum disorder (ASD) (Souders et al. 2009). Increased sleep onset latency and night wakings, decreased sleep efficiency, and variable sleep patterns have been identified more frequently among children with ASD in comparison to typically developing peers (Vriend et al. 2011). Children with ASD are affected by additional side effects of poor sleep, among which increased stereotypy, decreased social skills, and increased aggression (Schreck et al. 2004).

Biology is pivotal to our understanding of the causes of sleep difficulties. Finger (1982) posited that all beings follow the circadian cycle of sleep and wake. Research, however, has shown differences between adult and infant sleep with infants experiencing quicker transitions between rapid eye movement (REM) and non-REM stages of sleep (Jin et al. 2013). Studies using electroencephalography have demonstrated a link between REM sleep and wakings. Thus, due to higher frequencies of REM sleep, infants are more likely to wake. These high frequency REM arousals in infants when combined with maladaptive parenting techniques can facilitate the development of sleep difficulties (Anders et al. 1992).

Behavioral interventions have demonstrated success with sleep disorders, with most studies reporting clinically significant improvements (Vriend et al. 2011). Behavioral interventions mostly rely on the principle of stimulus control, defining falling asleep as an operant behavior under the control of discriminative stimuli (e.g., darkness, cool temperatures, and bedding) and sleep as a reinforcer itself (Bootzin 1977).

A central assumption of stimulus control interventions is that if consistent sleep is to occur, steps in the behavior chain that precedes sleep must come under the control of suitable cues or discriminative stimuli (Bootzin 1977). As is the case with any behavior, discriminative properties are obtained by stimuli in the environment which reliably signal the availability of reinforcement, in this case sleep. Motivating operations also play a central role in sleep onset, as they can increase or decrease the value of sleep as a reinforcer and

consequently increase or decrease the likelihood of an individual engaging in behaviors that have previously led to sleep. Relevant motivating operations for sleep are the quality, duration, and time elapsed since previous sleep (Laraway et al. 2003). Knowledge of stimulus control and motivating operations have formed the basis of the most widely used sleep strategies, positive routines, and bedtime fading, which in previous research have generally been combined in multicomponent packages targeting sleep improvements.

Positive routines. Bedtime routines are an easy to implement, low-cost means to improve sleep that reduces non-compliance and increases constructive sleep behaviors (Kodak and Piazza 2008). Positive routines emulate a successful intervention within adult insomnia, namely, stimulus control therapy (Perlis et al. 2011), which states that poor sleep results from absence of stimulus control and therefore establishing strong, appropriate discriminative stimuli for sleep can result in a reduction in sleep disorders. Positive routines consist of a series of five to seven pleasant calming activities undertaken during wakefulness to facilitate sleep onset (Gruber et al. 2011). Studies have noted that routine occurrence rather than content is important (Kodak and Piazza 2008). How distinct and consistent a cue is depends on how often the behavioral sequence is practiced. Through repeated practice of each step in the sequence, the behavioral chain terminating in sleep onset becomes stronger. Additionally, if discriminative stimuli which cue sleep onset are encountered when the child wakes, independent sleep resumption is more likely. Therefore, by training appropriate cues at bedtime, the length of nighttime awakenings may also decrease. Positive routines are in most occasions implemented by caregivers, the primary change agents for children with ASD, who often make use of visual schedules to facilitate understanding and adherence to the positive routine (Honaker and Meltzer 2016; Sanberg et al. 2018).

Bedtime fading. The central aim of bedtime fading is to manipulate the sleep-wake cycle so as to increase the likelihood of sleep. Bedtime fading involves temporarily moving bedtime to more closely coincide with the child's natural sleep

onset and then fading this earlier if sleep onset latency remains short to more closely approximate developmental norms and parental wishes (Morgenthaler et al. 2006). Bedtime fading facilitates rapid sleep initiation preventing inappropriate behaviors from being practiced in bed, as the more inappropriate behaviors are practiced, the more likely they are to access reinforcement. By remaining awake and out of bed longer, a motivating operation emerges which establishes sleep as a potent reinforcer and increases the likelihood of behaviors that facilitate sleep. A scheduled wake time is also established, and sleep is not permitted outside of established sleep times. This further acts to establish sleep as valuable. Faded bedtime has also been noted to closely resemble sleep restriction therapy (Perlis et al. 2011), which has been found effective in reducing adult insomnia.

A number of advantages to bedtime fading have been noted. The intervention is run at a time which decreases the likelihood of parental fatigue and as such minimizes implementation errors (Piazza and Fisher 1991). Further, the likelihood of non-compliant behavior emerging is reduced, as children are only instructed to go to bed once motivation is high. Two biological factors aiding the procedure have been noted. First, increased sleep pressure makes rapid onset more likely. Secondly, a steady bed and wake time may regulate the child's circadian rhythms and enhance synchronization with the desired schedule (Piazza and Fisher 1991).

The use of bedtime fading was first presented by Piazza and Fisher (1989), who discussed its use for a 6-year-old girl with attention deficit hyperactivity disorder who experienced multiple sleep difficulties. The intervention was effective for increasing sleep duration. The first published study occurred at a later date (Piazza and Fisher 1991). Within this, bedtime fading was used for two typically developing children for whom other sleep interventions had been ineffective. Results found the intervention effective in increasing total sleep duration. This study was based on the work of Adams and Rickert (1989) who combined positive routines with a simplistic version of bedtime fading. Piazza and Fisher's (1991) study however removed positive routines and evaluated bedtime

fading alone. Piazza and Fisher (1991) conducted a follow-up study in which bedtime fading and response cost were used to increase sleep duration for four individuals with intellectual disabilities aged between 3 and 19. Response cost is defined as removing the child from their bed for a predetermined period of time if they do not fall asleep within the designated sleep onset latency or if they awake during night. All four participants demonstrated increased nighttime sleep duration and decreased daytime sleep. Similar results have been found by other researchers.

Current Knowledge

In recent years, a significant number of studies have examined the effectiveness of positive routines and bedtime fading.

Positive Routines: Positive routines were first utilized by Milan et al. (1981) as a means to combat negative side effects experienced with extinction. Instead, a fading and chaining intervention was used to alter child sleep behavior. Participants were three children with severe intellectual disabilities. For all participants, the intervention was successful in reducing nighttime tantrums and increasing sleep duration. A second study conducted by Adams and Rickert (1989) compared positive routines with graduated extinction and a control. The dependent variable again was bedtime tantrums. Participants consisted of 36 typically developing toddlers. Similarly to Milan et al. (1981) a bedtime fading component was added though not termed as such. This was the first use of bedtime fading and went on to form the basis of future research. Both treatment groups demonstrated comparable decreases in bedtime tantrums. However faster effects and greater parental satisfaction were found for positive routines compared to graduated extinction.

A number of studies have utilized positive routines within multicomponent interventions implemented by parents in the home environment, combining positive routines with extinction-based strategies or sleep scheduling (e.g., Christodulu and Durand 2004; Knight and Johnson 2014). Other studies have evaluated positive routines in isolation. For example, Mindell et al. (2009) evaluated the

efficacy of positive routines for 405 typically developing toddlers aged between 7 and 36 months. Positive routines were found to be effective at reducing sleep onset latency and night wakings, while a follow-up study found positive outcomes were maintained. A more recent evaluation of the efficacy of positive routines was undertaken by Mindell et al. (2014) who sought to examine the impact of routine “dose” on intervention efficacy. Dose was defined as the amount of routine exposure the child received. This study was cross-cultural with over 10,000 typically developing participants. Positive routines were found effective with routine exposure negatively correlated with bedtime difficulties.

In sum, positive routines are a parent-friendly intervention that allows for individualization, while reducing parental fatigue and increasing implementation accuracy (Kodak and Piazza 2008). Interventions which occur at the child’s bedtime have shown to be more acceptable (Honaker and Meltzer 2016). Bedtime non-compliance has also been noted to decrease as a result of intervention (Morgenthaler et al. 2006). These benefits led Durand (1998) to consider positive routines an errorless approach.

Bedtime Fading. In a further extension of the behavioral literature focusing on sleep, Piazza et al. (1991) evaluated the efficacy of bedtime fading combined with response cost for three children with Rett syndrome aged 4–8 years. All participants demonstrated increased appropriate sleep, decreased daytime sleep, and decreased challenging behaviors. In a further study, a comparison of bedtime fading with response cost and sleep scheduling was also evaluated (Piazza et al. 1997). Results indicated that sleep duration increased more for those in the bedtime fading condition compared to the response cost and sleep scheduling conditions. These studies suggest that bedtime fading combined with response cost is effective in improving overall sleep patterns.

More recent empirical evaluation of bedtime fading is multicomponential in nature. Christodulu and Durand (2004) examined positive routines and bedtime fading for four young children with developmental disorders aged 2–5 years. Results indicated increased total sleep duration for all participants. Vriend et al. (2011) evaluated the efficacy of a multicomponent intervention for three

individuals with ASD and primary insomnia. The intervention consisted of parent-implemented bedtime fading and response cost. Increased sleep efficiency and decreased sleep onset latencies were noted. Results were maintained at a 3-week follow-up. More recently, Sanberg et al. (2018) evaluated the efficacy of bedtime fading combined with response cost on decreasing sleep disturbance in children with ASD. This intervention was found to be effective at reducing sleep onset latency and bedtime resistance. Research to date supports the efficacy of bedtime fading in combination with other interventions. Gradisar et al. (2016) conducted a randomized control trial comparing the efficacy of graduated extinction, bedtime fading, and sleep education on sleep onset latency in infants. Significant improvements were achieved for both graduated extinction and bedtime fading groups. Cooney et al. (2018) investigated the utility of group parent education to train parents in the implementation of bedtime fading for preschool children. Improvements in sleep onset latency night wakings were noted and maintained at a 2-year follow-up.

Limited research has evaluated bedtime fading in isolation. DeLeon et al. (2004) sought to evaluate the efficacy of bedtime fading to reduce night wakings in a 4-year-old boy with ASD. Results noted an 81% reduction in night wakings and an 82% reduction in self-injurious behavior.

To date only one study has compared the efficacy of positive routines versus bedtime fading. Delemere and Dounavi (2017) compared the efficacy of parent-implemented bedtime fading versus positive routines on sleep onset and night wakings of six children with ASD aged 2.5–6.5 years. While positive results were found for both groups, greater gains were noted for participants of the bedtime fading condition.

Future Directions

It is clear that both positive routines and bedtime fading have demonstrated efficacy in decreasing sleep difficulties in children. The apparent efficacy of stimulus control techniques for sleep is beneficial as it minimizes the need to utilize

extinction-based protocols which often present multiple side effects (Jin et al. 2013). Reid et al. (1999) noted a dropout rate of 20% of parent participants from extinction-based interventions due to a reluctance to ignore crying. Stimulus control interventions in comparison do not result in prolonged periods of crying or increased rates of challenging behaviors (Burke et al. 2004). A key advantage of stimulus control interventions is the facilitation of sleep-related skill acquisition by children, in contrast to extinction that does not permit this (Cortesi et al. 2010). Finally, intervention implementation at the child's bedtime is advantageous, as it minimizes parental fatigue increasing implementation fidelity (Kodak and Piazza 2008). The high social validity, treatment fidelity, and acceptability scores obtained across several studies (e.g., Delemere and Dounavi 2017) also support the positive effects of implementing sleep interventions at this time. This suggests that future research on stimulus control interventions rather than extinction-based approaches is warranted.

Functional relations surrounding sleep require further investigation. Functional assessments are the hallmark of behavioral interventions (Hanley et al. 2003). Sleep problems have been exempt from such analyses, although they represent a severe challenge for children and families. Albeit effective interventions have been documented, the conditions under which each strategy should be implemented to maximize benefit have not been established. Jin et al. (2013) reported the efficacy of individualized function-based sleep interventions for young children. The lack of environmental contingency evaluation of participants' sleep difficulties may have adversely impacted results in research to date. Future research should examine the function of sleep problems and use this to guide intervention design and implementation.

Parent-Professional Collaboration

► Parent-Professional Partnership

Parent-Professional Partnership

Debra Dunn

The Center for Autism Research, The Children’s Hospital of Philadelphia, Philadelphia, PA, USA

Synonyms

Family-centered programming; Parent involvement; Parent-professional collaboration

Definition

A Parent-Professional Partnership is a collaborative relationship between the parent of a child with

a disability and a professional who is involved with helping that child. Educators are the professionals most frequently thought of when referencing a Parent-Professional Partnership. However, any professional who provides a direct or indirect service to the child with the disability or to the child’s family, or who is involved in the policies affecting the child, can be a part of this collaborative partnership. In addition to educators, other professionals with whom a parent may form a partnership include policy makers, trainers, and therapists.

The Individuals with Disabilities Education Improvement Act of 2004 (IDEIA) specifically endorses partnerships between parents and educators. The IDEIA encourages parents to be actively involved in their children’s education and empowers them with rights and responsibilities with respect to the assessment process and the development of the individualized education program. In particular, the early intervention system requires a family-centered approach that takes family values and priorities into account, which necessitates the development of a Parent-Professional Partnership.

Parent-Professional Partnerships exist in many venues outside the education setting as well. For example, partnerships are frequently formed between parents and professionals delivering therapies and services outside of the education setting (e.g., through a state’s mental health or behavioral health system or through private practice). Parent-Professional Partnerships may also be created to train teachers, staff, or college students pursuing a career in special education. On a larger scale, federal, state, and local agencies or advisory groups also rely on Parent-Professional Partnerships by having representation from both professionals and parents who work collaboratively to set policies for children with disabilities. For example, every state has a special education advisory committee (SEAC), and many of these committees exist at the local level as well.

Effective Parent-Professional Partnerships are based on open communication, commitment, trust, sensitivity, and mutual respect. Both sides must recognize the importance of what the other can contribute. While professionals bring expertise on interventions, resources, specialized

instruction, and available programming, parents are the experts of their children. While professionals often see the child in only one environment, parents are frequently accustomed to dealing with multiple service systems and have the benefit of knowing what has been successful or unsuccessful in the past. Parents can also facilitate communication among service providers, thus assisting with continuity and convergence of services.

Obstacles to the Parent-Professional Partnership include attitudinal barriers, socioeconomic and cultural barriers, communication barriers, and fear. Yet the benefits of an effective Parent-Professional Partnership outweigh the difficulties in overcoming these hurdles: Research has shown that family involvement is one of the most important factors in ensuring a child's success. Parent training organizations, support groups, and resource centers are available to help prepare parents for this collaborative role, and increasingly professional organizations are devoting time to train their constituents to work as partners with parents.

Parents' Use of Internal State Language with Toddlers with ASD

Tyler McFayden¹ and Virginia Slaughter²

¹Department of Psychology, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

²University of Queensland, Brisbane, QLD, Australia

Definition

Internal state language (ISL): Internal state language is vocabulary used to convey others' or one's own inner perceptions, desires, emotions, and cognitions; also referred to as mental states (Baixauli et al. 2016). ISL includes several categories, including terms referring to perception, physiology, emotion/affect, volition/ability, cognition, and moral judgment/obligation. Examples of categories of ISL, adapted from Bretherton and Beeghly (1982), are below in tabular form (Table 1). ISL is frequently studied in relation to theory of mind and emotion socialization in childhood (Bretherton and Beeghly 1982).

Historical Background

Internal State Language (ISL) is pervasive in human conversation. Parents label and comment on their children's internal states starting in infancy (Meins et al. 2001). As they grow,

Parents' Use of Internal State Language with Toddlers with ASD, Table 1 Categories and exemplars of ISL

ISL category	Words	Examples of ISL verbatim productions from children
Perceptual	See, look, watch, hear, listen, taste, smell, feel, hurt	"I'm going to be a cloud in the sky so you can't see me."
Physiological	Hungry, thirsty, sleepy, tired, sick	"Me not sleepy, mommy."
Emotional/affective	Happy, fun, proud, feel, better, good, like, love, surprised, sad, angry, scared, messy	"Santa will be happy if I pee in the potty."
Volition/ability	Want, need, have to, can	"My baby needs me."
Cognition	Know, think, remember, forget, understand, guess	"Dolly knows where it is."
Moral judgment/obligation	Good, bad, naughty, may, let, must, should, have to	"Matthew won't let me play!"

children are continuously exposed to ISL in conversation with parents, siblings, and peers. This is an important factor for children's social-emotional development (Tompkins et al. 2018).

Children begin to speak about mental states usually in the second postnatal year (Bretherton and Beeghly 1982). By 2 years of age, children refer to a range of feeling states in themselves and in others and discuss the causes of characters' feelings in book reading, pretend games, and conversations with others (Dunn et al. 1987). Talk about cognitions, desires, and feelings increases between ages 2 and 4 years, with cognitive talk continuing to increase from 4 to 6 years of age (Jenkins et al. 2003), while other ISL remains consistent or slightly declines.

Understanding and talking about mental states is critical for many developmental skills, including sharing, understanding emotions, prosocial behavior, and theory of mind (Brownell et al. 2013). Observational studies conducted with young, typically developing children indicate

that increases in internal state labelling are associated with greater cooperation, conciliatory behavior with siblings (Dunn and Munn 1986), and greater concern and attention to adult distress and emotions (Garner 2003).

In addition to children's ISL, researchers have investigated parents' ISL. The two are related, such that parents who use a lot of ISL in conversation have children with relatively advanced ISL (Taumoepeau and Ruffman 2008). Parents' ISL also predicts the child's later theory of mind, even when controlling for language, age, parent education, and verbosity (Ruffman et al. 2002).

Given the strong predictive power of parents' ISL to children's social-emotional development, it is understandable that parental ISL would be of substantial interest in the study of Autism Spectrum Disorder. A toddler's use of internal state language is reflective of their theory of mind (Capps et al. 1999), that is, understanding other people as separate beings with their own thoughts, feelings, and concerns. However, children with ASD demonstrate difficulties with ISL: Children with autism are less likely to identify causes of characters' internal states or to elaborate on internal emotions or cognitions (Capps et al. 1999). Since core deficits of ASD include social-communication skills and theory of mind, ISL provides an interesting vantage point for the study of the development of theory of mind and social-communication skills in this clinical population.

Current Knowledge

Do Parents of Children with ASD Produce Less Internal State Language?

Some work has noted that parental ISL use with children with ASD is qualitatively and quantitatively different than with typically developing (TD) children. For instance, in a case study conducted with a 43-month-old female with ASD, parental language was recorded and analyzed over a 3-day period. Results indicated that the mother and father used ISL terms in 33% and 24% of their utterances, respectively (Kay-Raining Bird et al. 2008). These values are

compared to other studies reporting percentages of ISL ranging from 33% to 60% for typically developing toddlers (Beeghly et al. 1986). In the case study, the most prominent ISL categories included sensory and desire utterances, which occurred more frequently than cognitive ISL categories. Parental elaboration or use of causal language – such as explaining why a story character may have felt a particular way – was minimal. Thus, both parents in this case used ISL less frequently and less explicitly than a parent of a TD child of the same age. This suggests that parental use of ISL may be qualitatively and quantitatively different for children with ASD, involving less ISL speech overall and fewer causal explanations.

However, other evidence suggests that there may be more similarities than differences in parental ISL towards children with ASD. For instance, during book reading with children ages 4–9 years of age, mothers of ASD-diagnosed and TD children produced narratives of similar length, similar numbers of word tokens, and were similar in the number of times they mentioned cognition, affect, and perception/attention (Slaughter et al. 2007). However, more subtle differences emerged when looking at how ISL was elaborated and clarified in these samples. Mothers of the ASD group produced significantly fewer clarifications and elaborations of cognition and affect terms. For instance, they were less likely to explicitly state the thoughts of characters, including explaining the source of information or noting discrepancies in how two different characters were thinking. After controlling for verbal mental age, maternal education, and maternal verbosity, clarification of affect was associated with theory of mind in the ASD group. These results suggest that while the length of utterances and communicative interchanges by parents to their children with ASD may be equivalent to those of TD peers, the content may be different. Parents of children with ASD may be less likely to elaborate and explain characters' inner thought and feelings.

These findings and conclusions were replicated in work by Hutchins et al. (2017), who compared story narratives of mothers of TD children to mothers of children with ASD (ages

4–11 years). Similar to Slaughter et al. (2007), the authors found that mothers did not differ in the overall amount of ISL talk, but that TD mothers made more causal and clarifying statements connecting internal states to external behaviors. In both groups, mothers who used more cognitive and affective clarifications rated their children as having better theory of mind than mothers who used less ISL. These results seem to confirm that children with ASD are exposed to similar amounts of ISL as their TD peers, but they hear fewer explanatory or clarifying statements about internal states. This could be an important area for intervention since children with ASD may particularly benefit from explanatory, clarifying talk about internal states of characters during play and reading (Slaughter et al. 2007).

However, it may be how parents *elicit* children's talk about emotions, more so than parental production of ISL, which influences children's social behavior (Brownell et al. 2013). For example, in a wordless picture book reading task with toddlers, Campbell et al. (2019) investigated parental ISL to three groups: infants at high risk for developing ASD (as indicated by having an older sibling with an ASD diagnosis) but who did not go on to develop ASD, infants at high risk who went on to develop ASD, and infants at low risk for developing ASD. Their results were consistent with other findings in that parents in all three groups used similar frequencies of overall ISL at 22 and 34 months of age. However, parents of children with ASD demonstrated less ISL elicitation from their infants than parents of low risk or high risk, non-ASD children. Thus, perhaps the difference-maker in these parent-child interactions is not the quality or quantity of speech input to the child but how well parents are drawing out ISL from their children. This is a promising area for future study.

For TD children, the quantity and quality of parental ISL influences a child's theory of mind and social cognition (Taumoepeau and Ruffman 2006). It is not yet clear if the same holds true for children with ASD. Mixed results indicate that theory of mind training – which typically incorporates internal state language – may, or may not, be effective for individuals with ASD (e.g.,

Fletcher-Watson et al. 2014). Although it stands to reason that exposure to explanatory ISL speech may improve ASD children's theory of mind, there has been no direct research on this topic. The efficacy of parent training to improve ISL, and its subsequent impact on theory of mind and/or social behaviors for children with ASD, are therefore promising areas for future research.

What Factors Influence Parental ISL Production?

Parental ISL production may vary depending on many characteristics, including the parent's own proclivities and preferences, their child's developmental abilities, and parental beliefs about their child's development (Beeghly et al. 1986). Parental beliefs, in particular, may be linked to how mothers and fathers parent their young children. Mothers with more complex beliefs about toddler and child knowledge (complex epistemologies) reportedly use mental state language more often to encourage child reflection, which results in greater frequency of mental state terms used by children (Hutchins et al. 2009). Similarly, parents of children with ASD reportedly use similar numbers of mentalistic descriptors when asked to describe their child, as compared to parents of TD children. However, the quality of those descriptors is significantly different (e.g., more negative; Kirk and Sharma 2017). Here again, parents of children with ASD seem to use similar amounts of mentalistic descriptors as TD parents, but those verbalizations are qualitatively different.

Parental ISL may also depend on the perceived conversational readiness of the child. Results from Slaughter et al. (2009) revealed that the earlier infants produced imperative gestures, the more frequently their mothers referenced internal, volitional states at 15 months of age. These results indicate that maternal communication about infants' wants and desires is linked to their infant's production of communicative gestures (Slaughter et al. 2009). This linkage of infant gestures to parental ISL is particularly interesting in the realm of ASD, as children with ASD typically produce fewer gestures and a decreased variety of gestures during parent-child interactions (Mastrogiuseppe et al. 2014). Therefore, infants

at greater risk for developing ASD may gesture less, reducing their parents' opportunities to use internal state language.

Another interesting interaction is present when considering the openness to emotions and emotionality of the parent. Previous works have indicated that variance in emotion-related socialization behaviors of parents – specifically the use of ISL – was explained partially by openness to emotional processes and children's personality (Mazzone and Nader-Grosbois 2017). Given the Broader Autism Phenotype account of Autism Spectrum Conditions (e.g., Wheelwright et al. 2010), parents of children with ASD may possess traits suggesting genetic liability to autism, including less emotional openness or a decreased ability to label emotions in others. As such, parents of children with ASD may naturally use less ISL in everyday interactions, including interactions with their children.

Lastly, there are demographic factors that impact parental ISL use with toddlers and children. One such factor is sex of the speaker and of the child. Although almost all research has been conducted with mothers, some work has looked into parental ISL by mothers *and* fathers to investigate the role of the sex of the caregiver. With typically developing toddlers, Jenkins et al. (2003) highlighted that mothers spend a higher proportion of their time talking about internal mental states than fathers. This finding held across all ISL categories. Furthermore, different caregivers may utilize ISL in different ways. LaBounty et al. (2008) found that each caregiver's use of ISL predicted unique constructs concurrently and later in a TD-child's life. While mothers' references to emotion and emotion causal explanatory language predicted children's concurrent emotion understanding, fathers' use of causal explanatory language referring to desires and emotions predicted children's concurrent and later theory of mind. The way in which mothers and fathers engage with ISL may also have gendered transmission to children. For instance, mothers and older siblings mention feeling states more frequently to TD girls than to TD boys. Accordingly, by 24 months of age, TD girls refer to their own feeling states significant more than

TD boys (Dunn et al. 1987). These sex differences have only just begun to be explored in ASD. One study found that girls with ASD verbalize internal states more often than boys with ASD, but that both girls and boys with ASD fall behind TD children in production of affective state words and ISL (Kauschke et al. 2016). The sex differences in parental ISL production and parent-child transmission of ISL is a significant future direction of research given the sex diagnostic discrepancy in ASD.

Summary

Parental internal state language is an important type of communication that contributes to a child's developing emotion socialization and theory of mind. ISL is used in upwards of one third of parental vocalizations to TD toddlers and children and may even be upwards of 50% of total vocalizations in book-reading tasks (e.g., Beeghly et al. 1986). However, it is not yet clear if these frequencies hold among parents with children with ASD. While some case studies suggest that the quantity and quality of parental ISL may be lower in families with a child with ASD, other observational studies suggest that parents of ASD children may, in fact, use the same number of utterances and ISL words. The differences, however, in ASD families are how explicitly parents label ISL and elaborate or clarify their ISL statements. While parents of TD children tend to use causal and explanatory ISL language with their children, parents with ASD children do not engage in the same practice of being explicitly causal when talking about internal states, even though children with ASD might benefit from such talk. These differences in parental ISL use may be due to many factors, including parental factors (e.g., parenting beliefs, epistemology, emotional availability, and gender) and child factors (e.g., communicative readiness, gestural production, developmental ability, personality, and gender). Importantly, parental ISL production is likely an interaction of parent and child factors that evolve and change over the course of development. Given the established connections

between ISL and socio-emotional outcomes such as theory of mind and certain social skills in TD children, parental ISL toward children with ASD is an important avenue for continued and future research.

Future Directions

Parental ISL is an under-studied area in the fields of clinical psychology and social-emotional development. Many avenues are pressing for future research, including paternal transmission of ISL (e.g., focusing on fathers' ISL use and the different types of activities that stimulate mothers and fathers to produce ISL spontaneously), sex differences in ISL within ASD samples (e.g., parental ISL to sons versus daughters, sex differences in the processing and use of ISL), and closer analyses of differences in ISL use by parents of children with ASD. While a few studies have used book-reading or structured play tasks to elicit ISL, future work should aim to increase external validity by investigating ISL in school settings, social settings with peers, and naturalistic family settings. These settings may include a variety of conversational partners, such as teachers, grandparents, and siblings; all of whom are understudied in their contributions to ISL for children with ASD. Future longitudinal work should also aim to better understand the developmental course and causal pathways of parental ISL. For instance, if gestural use by the infant is a signal to parents to commence using mental state language, this is a hypothesis that could be tested longitudinally. Finally, careful investigation of associations between exposure to ISL and social-cognitive outcomes for children with ASD may inform novel ISL-targeted interventions for this clinical group.

Definition

Paroxetine is a selective serotonin reuptake inhibitor (SSRI) used to treat depression, social anxiety

disorder, obsessive-compulsive disorder, and post-traumatic stress disorder. Paroxetine is available in immediate- and controlled-release formulations and is the most potent inhibitor of serotonin reuptake compared to currently available SSRIs. Originally developed in the 1970s, its side effects include constipation, sedation, sexual dysfunction, discontinuation syndrome, and weight gain. Given the growing body of research that suggests that abnormalities in serotonin function are linked to autism, the use of SSRIs in patients with autism has grown. Case studies of patients with autism using paroxetine indicate mixed results, with reports of improved and worsened aggressive behavior.

Participation of Black and African-American Families in Autism Research

Wendy E. Shaia¹ and Sarah Dababnah²

Baltimore, MD, USA

Definition

The majority of research articles focused on autism spectrum disorder (ASD) do not provide sufficient data on race and ethnicity (Pierce et al. 2014); thus, the level of participation of racial and ethnic minorities in ASD research is largely unknown. While approximately 13% of the US population identifies as Black (US Census Bureau 2018), Black children and their families are underrepresented in ASD research (Burkett et al. 2015; Hilton et al. 2010; West et al. 2016). Yet, racial disparities concerning timely ASD diagnoses and healthcare access are well-documented (e.g., see Thomas et al. 2007); and service delays persist for Black children regardless of family socioeconomic status (Magaña et al. 2012; Mandell et al. 2010). In this entry the term “Black” refers to people of the African diaspora, including those of African American descent, African-Caribbean descent, African-Latinx descent, and those from the African continent.

Historical Background

While research on Black families is still emerging, studies have identified potential factors leading to racial disparities in ASD service access and quality. Primary healthcare provider bias toward Black families may negatively impact parent-provider relationships and ASD screening of children, thus delaying children’s access to valuable early intervention (Burkett et al. 2015; Dababnah et al. 2018). Black parents report reluctance to share ASD-related concerns with their doctors (Donohue et al. 2017), in part because parents often encounter providers who disagree with them about the presence of ASD symptoms (Neuhaus et al. 2018; Dababnah et al. 2018; Pearson and Meadan 2018). Miscommunication between healthcare providers and parents, as well as cultural differences in symptom interpretation, can also lead clinicians to diagnose children differently based on race (Barton et al. 2012; Burkett et al. 2015; Mandell et al. 2007).

Current Knowledge

A recent study outlined several barriers and facilitators to the involvement of Black children and their families in ASD research (Shaia et al. 2019). The study directly solicited the perspectives of 22 parents and other primary caregivers of Black children with ASD using qualitative interview methods. The majority of participants were mothers of Black children with ASD; the remaining participants were grandmothers and other female caregivers. Approximately half of the participants had a high school education or less and annual household incomes less than \$50,000. Service providers referred over one-third of participants to the study; the remaining parents heard about the study from social media, schools, and community sources.

Figure 1 summarizes facilitators, barriers, and recommendations to increase Black children’s involvement in ASD research. Table 1 lists suggestions from caregivers of Black children for research recruitment sources (Shaia et al. 2019). The most common suggestion was school

recruitment; caregivers also wished to hear about studies from other parents and trusted sources. Notably, researchers should consider recruitment resources other than service providers, as Black

caregivers often do not see service providers as trustworthy information sources (Burkett et al. 2015).

Facilitators

Desire to Contribute to Inclusive Research
Shaia et al. (2019) found that caregivers were motivated to advance and contribute to ASD research. A common motivating factor included caregivers’ desire to help others learn more about ASD, particularly research specifically targeting Black families. These findings were consistent with the Burkett et al. (2015) study of Black children with ASD and their families, which

reported families tried to increase ASD awareness and education in their communities.

Seeking Information and Support

Some caregivers were motivated to take part in research in order to receive information and/or resources for their own children. Another related factor was increasing support for themselves, particularly to address isolation and to speak with others who understood their challenges related to raising a child with ASD.

Engaging with Culturally Responsive Research Team Members

Positive interactions with research team members were important facilitators that increased some caregivers' willingness to become involved in research. Shaia et al. (2019) reported study participants stated that it was important the interviewer identified herself as a Black mother of a child with ASD.

Barriers

ASD Stigma and Denial

Shaia et al. (2019) found stigma (from both inside and outside the Black community) was a potential barrier to Black families' involvement in ASD research. Their study also reported stigma was related to denial of the ASD diagnosis, which made parents reluctant to participate in ASD studies. Several other research studies focused on Black families have also identified ASD-related denial and stigma (Burkett et al. 2015; Dababnah et al. 2018; Pearson and Meadan 2018).

Distrust of Research

Suspicion and distrust of the research process was a potential barrier to Black families' engagement with research (Shaia et al. 2019). Concerns about sharing information, particularly with non-Black investigators, were common among caregivers raising Black children with ASD. Other research has similarly found perceived power differentials and cultural differences can be a barrier to Black participants' involvement in studies (Alvarez et al. 2006).

Lack of Time or Interest

Shaia et al. (2019) reported study participants cited lack of time, feeling overwhelmed, and

general disinterest as barriers to research involvement. Dababnah et al. (2018) found poverty and other external stressors can be barriers to following up on ASD service referrals, thus suggesting families who are experiencing poverty and other stressors may require additional supports to engage in research.

Inaccessible Research Materials

Difficulty in understanding research materials due to low literacy is a barrier for some potential research participants. Shaia et al. (2019) found some study participants were uncomfortable sharing their thoughts when the interview was being recorded. Skinner et al. (2008) likewise concluded lower educational levels were barriers to research participation.

Future Directions

Literature inclusive of Black children with ASD and their families is developing. Investigators should consider diverse community-based methods to increase involvement of Black participants, including schools, community services, and faith-based organizations. Partnerships between ASD researchers and community-based organizations can potentially facilitate recruitment of Black and other underrepresented children and their families.

Researchers should be aware of potential barriers to the involvement of Black families in ASD research, including ASD stigma, caregivers' denial of the ASD diagnosis, lack of time to dedicate to studies, and low literacy. Furthermore, Black parents' distrust of the research process or investigators can limit their willingness to engage in research. On the other hand, several factors can facilitate Black families' participation, such as their desire to contribute to studies that advance knowledge of ASD in their communities; to identify peer support; and to locate information for their children. In order to counteract possible parent distrust of the research, investigators should ensure their research team members are representative of the target study sample and engage with potential participants in a warm and empathic manner. In particular, research teams should be

aware of the many ways in which their personal attitudes and characteristics may influence participants' comfort and willingness to engage fully in studies. Figure 1 lists additional recommendations to increase participation of underrepresented families. Structured text and visual representations can aid individuals with low literacy to access research materials. Food, transportation support, childcare, and data collection in nontraditional settings (e.g., homes, libraries) can encourage participation. Researchers should also be careful to minimize the time needed to participate in studies.

Shaia et al. (2019) focused on the perspectives of urban caregivers of Black children with ASD. Like some other studies, most of the participants were mothers (Pearson and Meadan 2018; Burkett et al. 2015). Future research should explore how to increase participation of suburban and rural families, as well as non-maternal caregivers. More studies are needed to understand specific methods to support Black families overcome stigma; approaches researchers should employ to recruit Black families to research; how to improve the quality of services families receive; and how to increase the accessibility of research materials for all participants. With the increase in ASD diagnoses across all races (Baio et al. 2018), it is important that future ASD research is more fully representative of the diversity of the ASD community.

Passive Group

Lorna Wing
Centre for Social and Communication Disorders,
Bromley, Kent, UK

Synonyms

Inactive; Unengaged

Definition

The various different sets of criteria for autistic disorders usually include repetitive routines, language abnormalities or mutism, clumsiness, and odd responses to sensory input, but all emphasize marked impairment of social interaction as a fundamental problem. Kanner (1943) and Kanner and Eisenberg (1956), in their definitions of early infantile autism, emphasized social aloofness and indifference as an essential criterion for diagnosis. Asperger (1944) described children with what he called “autistic psychopathy,” whose pattern of social interaction was active, initiating contact with other people, but inappropriate in form.

Wing and Gould (1979) and Wing (1981) suggested that these authors were describing different aspects of an “autism spectrum.” This spectrum included those who were “aloof and indifferent” to others, those who were “passive” in their social interaction, and those who were “active but odd” in their approach to others. It must be emphasized that these groups merge into each other – there are no sharp dividing lines. It is also possible for someone to change from one type to another in their pattern of social behavior with increasing age or even in different environments.

The typical passive child does not make social approaches but accepts approaches from others. He or she may make eye contact, especially if the person approaching them makes positive effort to obtain eye contact. Many passive children are amenable and willing to do as they are told, so they can be accepted into a group of children playing together. The passive child will often accept the role assigned to him or her, such as that of a baby in a game of mothers and fathers. But, when the game is over, the passive child may continue in the role while the others turn to other pursuits. Passive children are much less likely than others in the autism spectrum to be difficult in behavior, to refuse to cooperate, or to have temper tantrums so do not draw attention to themselves (but see description of PDA below). However, Wing and Shah (2006) found in a study of individuals with autism spectrum disorders and a history of catatonic features, who developed catatonic deterioration, that this pattern occurred significantly more often in those with a history of social passivity. The clinical picture included movement problems (slowness and difficulty in initiating movements unless prompted, odd gait, odd stiff posture, freezing during actions, difficulty crossing lines, and inability to cease actions) and behavior problems (impulsive acts, bizarre behavior, awake at night but sleeping in the day, incontinence, and excited phases). In addition, there was marked reduction in the amount of speech or complete mutism.

In recent years, attention has been given to the prevalence of autism spectrum conditions in females. Attwood (2007) found that girls are more likely than boys to be passive, and, for this reason, their autism often remains undiagnosed.

Kopp and Gillberg (1992) and Kopp et al. (2010) have reported that girls are much more likely than boys to refuse demands passively, thus fitting into the group called pathological demand avoidance (PDA) (Newson et al. 2003).

In the past, it has been assumed that the passive group is markedly less common than the aloof or the active but odd groups. However, the recent rise of interest in this group, especially its prevalence in females, may change this view of passivity in autism. It is to be hoped that, in future, research will be carried out into the neurology underlying this mode of presentation.

Pathological Demand Avoidance (PDA)

Richard Woods
Independent Scholar, Nottingham, UK

Synonyms

Autism spectrum disorder and PDA traits (O’Nions et al. 2018); Extreme demand avoidance (Gillberg 2014); Newson’s syndrome (Ogundeell 2018); Pathological demand avoidance syndrome (Newson et al. 2003); Rational demand avoidance (Milton 2017)

Definition

Elizabeth Newson developed the concept of pathological demand avoidance (PDA) to describe a subset of children referred to her clinic based in Nottingham, UK, in the 1970s (Newson et al. 2003). Newson applied the term PDA to children that were traditionally diagnosed as either having pervasive developmental disorder-not otherwise specified or atypical autism, yet both parents and clinicians thought these terms did not adequately describe the child’s presenting difficulties (Newson et al. 2003). Consequently, PDA was first proposed in 1980 as a distinct pervasive development disorder with the following behavior profile (Gillberg 2014): consistent resistance to every day demands, ease at role-play and pretend play, language delay due to passivity, lability of mood and impulsivity due to need for control, neurological involvement, obsessive behavior, passive early history, and surface sociability that lacks social identity/pride/shame (Newson et al. 2003).

The modern profile provided by a charity has been reduced by removing delayed speech development, neurological involvement, and passive early history (Green et al. 2018). This is due to focus on diagnosing PDA as a specifier for education support, producing autism spectrum disorder + PDA traits diagnosis by some UK clinicians (O’Nions et al. 2018). However, the higher prevalence rates being reported than Newson and colleagues originally observed (Green et al. 2018) are generating concerns about whether these profiles are representing the same underlying condition. PDA is viewed as clinically useful (Christie 2007; O’Nions et al. 2016), due to its behaviors and educational needs being distinct from autistic persons. These will be explored later.

PDA is frequently contrasted against autism profiles, with growing interest arising from parents, clinicians, and educational practitioners (Christie 2007; Langton and Frederickson 2016). A medium-size early investigation compared PDA to classical autism and Asperger’s syndrome. This study suggested that the following behaviors are more common in PDA than established autism subtypes (Newson et al. 2003): (1) strategies used for avoidance being socially manipulative, such as by distracting the adult, acknowledging the demand but excusing themselves, physically incapacitating themselves, and retreating into fantasy and role-play (these are examples of demand avoidance); (2) not identifying themselves as a child; (3) instantly changing mood; (4) taking on second-hand roles such as those of a teacher; and (5) their obsessions being often focused on other persons. Significantly, PDAers (preferred terminology of those identified with PDA) make more sustained eye contact than those with autism (Newson et al. 2003). Contemporarily, research into demand avoidance behaviors indicate that they could be described as strategic instead of “manipulative” and are also identified with many triggers of changes in mood or avoidance ranging from uncertainty to novelty (O’Nions et al. 2018); the latter is also expressed by autistic persons, highlighting the overlap between the PDA and autism profiles. While PDA has a behavior profile, this is not proof of its existence as a separate entity, and so it has many competing ontologies which are discussed next.

As a proposed syndrome, there are various attempts to explain and categorize PDA, which due to its omission from the diagnostic manuals is fiercely debated, in part because of PDA lacking substantial and compelling evidence to settle the debates for its inclusion into the diagnostic manuals (Green et al. 2018; O’Nions et al. 2016; Woods 2017). Previously, PDA was not included in International Classification of Diseases 10th Revision, neither is it recognized in the 11th Revision of the International Classification of Diseases (World Health Organisation 2018). Some view PDA as a pervasive developmental disorder (Newson et al. 2003). The dominant ontology views PDA as part of the autism spectrum (Christie 2007; Langton and Frederickson 2016; O’Nions et al. 2018), as a consequence of commonly referring to umbrella pervasive developmental disorders as autism spectrum disorders. Additionally, arguing against debating it’s ontologically, as it distracts from diagnosing PDA and thus utilizing its strategies (Christie 2007).

PDA’s less widely accepted ontologies range from it being autism, a product of autism interacting with its comorbidities in a person (Green et al. 2018), a female form of autism, variations of attachment disorder or personality disorder (Christie 2007), and an expression of autistic trauma (Milton 2017). Particularly, the behaviors associated with the PDA profile overlap with common comorbidities in autism, specifically attachment disorder (Milton 2017), anxiety disorder, attention deficit and hyperactivity disorder, conduct disorder, and oppositional defiant disorder (Green et al. 2018). PDA behaviors may eventually be shown to have heterogeneous origins and mechanisms involving many comorbid conditions (Gillberg 2014). Lastly, its cultural construction is being questioned, notably as the commodification of autism, by pathologizing autistic self-advocacy (Woods 2017), via the double empathy problem, and how different autism stakeholders frequently have different outlooks compared to each other, autistic persons self-agency is pathologized (Milton 2017).

Much of the ontology debates focus on the cause of high anxiety levels found in PDA. The dominant ontology, as a form of behaviorism (Milton 2017), views the high anxiety level to

be intrinsic to the PDAer (Green et al. 2018). Conversely, its critiques contest that the demand avoidant behavior is caused by anxiety through an interactive, transactional process, wherein differences in the subjective experiences of PDAers render different types of activities aversive compared to the experiences of neurotypicals, promoting anxiety and avoidant behavior (Green et al. 2018; Milton 2017). Until an overwhelming empirical case is presented or it is adopted in the diagnostic manuals, there will be ample debate and confusion over the nature of PDA. Nonetheless, PDA has specific strategies and so potentially remains clinically relevant; for its diagnostic and screening tools, see O’Nions et al. (2014) and (2016).

Phil Christie assisted Elizabeth Newson in the development of PDA as a concept and later refined its educational strategies with input from staff at an autism specialist school (Christie 2007). The strategies for PDA include having a specific keyworker to build a trusting relationship, making demands in an indirect way rather than using direct language, avoiding conflict, being flexible, and adapting and negotiating by providing choices to pupils. Other recommendations were to develop a positive relationship, providing indirect praise, using humor to control the child, and use of role-play, novelty, and variety in lesson material to engage the child capturing their interest (Christie 2007). Newson et al. (2003) argued that these strategies are needed because traditional autism strategies emphasizing adherence to routines and structure reportedly do not work on those with PDA. Notably PDAers are disruptive in specialist autism classes and have high exclusion rates, necessitating these precise strategies, which is an important motivation for clinical recognition or diagnosis of PDA (Christie 2007). Pertinently, the PDA strategies are not to be practiced separate from autism strategies, and each individual is to receive bespoke support.

Langton and Frederickson (2016) explore the educational needs of pupils with PDA, comparing their results to those for autism; their findings suggest that need for extra support for PDA is no more than that of autism and cast doubts about the need for an additional diagnostic label of PDA. Critique of PDA strategies includes that in the time since

Newson’s description of PDA, there has been a move away from rigidly practiced educational support to bespoke packages (Green et al. 2018). Milton (2017) argues that many of PDA strategies are suitable for other children and that many autism strategies do not work with autistic persons. Though for the foreseeable future its ontology is contested, there is an urgent need for more research into it and adoption of PDA strategies.

Patricia Howlin

Iliana Magiati
Department of Psychology,
National University of Singapore,
Singapore, Singapore
School of Psychological Science, University of
Western Australia, Crawley, WA, Australia

Emeritus Professor Patricia Howlin

BA, University of Sheffield, UK (1967); MSC
Clinical Psychology, Institute of Psychiatry,

London (1968); PhD, Institute of Psychiatry,
London (1979); Fellow, British Psychological
Society (1990).

Major Appointments (Institution, Location, Dates)

Emeritus Professor Patricia Howlin held her first academic appointment as lecturer and then senior lecturer at the Institute of Psychiatry (IOP) at King's College London, UK from 1973 to 1992. She subsequently became a professor in clinical psychology at St. George's Hospital Medical School, University of London, UK. In 2006, she was appointed to the first Chair of Clinical Child Psychology in the UK at the Institute of Psychiatry, Psychology and Neuroscience (IOPPN), King's College London, until her retirement from full-time academia in 2014. She continues to be actively involved in research and teaching and is currently an emeritus professor of clinical child psychology at the IOPPN and a professor of developmental disability at the University of Sydney, Australia. She is also an adjunct professor at Curtin University, Western Australia, and Griffiths University, Queensland, and visiting professor at the Oslo University Hospital, Norway.

Major Honors and Awards

Prof. Howlin has received numerous honors and awards throughout her professional career. She was made a fellow of the British Psychological Society in 1990. More recently, in 2009, the Society for the Study of Behavioural Phenotypes, UK named their annual lecture after her (the Patricia Howlin Prize Lecture), while the Autism Association of Western Australia honored her for her services to autism. In 2013, she won the 2013 International Society for Autism Research (INSAR) Lifetime Achievement Award, and in 2015, she was honored for her contributions to autism research by the German, Austrian, and Swiss Society for Research in Autism Spectrum Conditions.

Landmark Clinical, Scientific, and Professional Contributions

In the late 1970s and early 1980s, Patricia Howlin together with Prof. Sir Michael Rutter and other colleagues from the Maudsley Hospital, London published a landmark systematic study – the first in the UK and one of the very first internationally – to demonstrate the effectiveness of parents as therapists for their children with ASD.

Among her many contributions to conducting high-quality, systematic research on issues that were always highly relevant to the needs and priorities of the autism community over the years, three aspects of her work in particular were most prominent in driving the field forward:

1. Her work in the 1970s, 1980s, and 1990s on systematically monitoring, evaluating, and reporting outcomes following behavioral, communication, social, and other comprehensive and focal interventions for individuals with ASD.
2. Her committed focus on the importance of research evidence and of “translating” empirical findings for families and clinicians to support them in making informed decisions.
3. Her research studies published in the 1990s and 2000s on adult outcomes. These were some of the largest and longest term internationally follow-up studies of individuals with ASD first assessed in childhood and followed up in adulthood, and were instrumental in documenting the poor educational, employment, and social outcomes of many adults with ASD, thus firmly placing the urgent need for research and support for adults with ASD on the ASD “map” and agenda.

Short Biography

Emeritus Prof. Patricia Howlin, Ph.D., is a consultant clinical psychologist and one of the world’s leading experts in autism spectrum and related neurodevelopmental/genetic disorders. Throughout her career, she has held a number of

academic and clinical appointments in the UK and internationally and has been involved in numerous collaborative and impactful research studies on the effectiveness of comprehensive and focal interventions, mental health and quality of life, and adult outcomes in ASD.

She is the author of more than 200 peer-reviewed research publications on ASD, which have been cited thousands of times. She has also written or cowritten many books on ASD and related conditions which have been translated into a number of different languages, of which *Treatment of Autistic Children* in 1987 with Michael Rutter, *Children with Autism and Asperger Syndrome* in 1998, and *Autism and Asperger syndrome – Preparing for adulthood* in 2004 are especially noteworthy for positively influencing and supporting families and professionals and for bringing scientific knowledge about ASD into the wider community.

In addition to her work in ASD, she has in more recent years extended her research focus to include other neurodevelopmental genetic disorders (i.e., Williams, Down, Angelman, and Cornelia de Lange syndromes). The recipient of multiple awards for her contributions to the field of ASD (including an INSAR lifetime achievement award and the Kanner Asperger award from the German Scientific Association for Autism Research), she was the founding editor of *Autism: the International Journal of Research and Practice*, while she currently serves as the President of the Society for the Study of Behavioural Phenotypes.

She continues to lecture internationally and holds a number of visiting appointments and collaborations with leading learning and research institutions in Japan, Australia, Norway, and elsewhere. In addition to her scientific contributions, she has worked closely over many years as an advisor, consultant, or advocate with the National Autistic Society (NAS) in the UK and many other voluntary and community organizations to improve awareness, understanding, support, and funding for individuals with ASD and other genetic neurodevelopmental conditions across all ages and levels of ability.

Patterning (Doman-Delacato Method)

Robert H. LaRue
Douglass Developmental Disabilities Center,
Rutgers, The State University of New Jersey,
New Brunswick, NJ, USA

Definition

The Doman-Delacato method, commonly known as patterning, is designed to improve a child's "neurological organization" through a series of specific prescribed sensory and motor experiences conducted on a rigorous daily schedule. These methods were presumed to improve functioning of the central nervous system in children with severe brain injuries (Doman et al. 1960).

Historical Background

The Doman-Delacato method is an approach to address neurological functioning by a series of

motor activities thought to alter the structure and function of specific areas of the brain. The method was developed by Glen Doman, a physical therapist, and Carl Delacato, a doctor of education. Doman and Delacato focused on maximizing the development of typical children. Spurring what Doman coined as the “Gentle Revolution,” he began to publish books aimed at teaching parents how to make their babies mentally and physically superior. Titles of their published books include “How to Teach Your Baby to Read” (Doman 1964b), “How to Teach Your Baby Math” (Doman et al. 1979), and “How Smart Is Your Baby?: Develop and Nurture Your Newborn’s Full Potential” (Doman and Doman 2006). Many of the titles from the Gentle Revolution series were coauthored with Doman’s son and daughter, Douglas and Janet Doman. Doman also published a book focused primarily on children with brain injury. In 1974, he published “What to Do About Your Brain Injured Child: Or Your Brain Damaged, Mentally Retarded, Mentally Deficient, Cerebral-Palsied, Spastic, Flaccid, Rigid, Epileptic, Autistic, Athetoid, Hyperactive Child” (Doman 1974).

In 1955, Doman founded the headquarters for the Institutes for the Achievement of Human Potential in the Philadelphia area. The IAHP (commonly referred to as “the Institutes”) is a nonprofit organization offering inpatient and outpatient treatment for brain-damaged children. The IAHP was created as a means for distributing the Doman-Delacato method, as described in a paper on neurological organization published in the *Journal of the American Medical Association* in 1960 (Doman et al. 1960). The IAHP has gained a global following, with offices in Japan, Italy, Mexico, Guatemala, Singapore, Brazil, Spain, and France.

Rationale or Underlying Theory

Temple Fay first applied the recapitulationist view of ontogenesis to children with nervous system disorders (Fay 1955), and the Doman-Delacato method is an extension of this work (MacKay et al. 1986). According to the recapitulationist theory, ontogeny (the development of an

individual from fertilized egg to its adult form) mimics phylogeny (the evolutionary history of a species). Stated another way, the development of an individual being imitates the evolutionary steps of the species. The recapitulationist school of thought was popular in the 1920s and 1930s. However, the theory has been refuted in modern biology and has not found support in the greater scientific community (Novella 1996).

Doman and Delacato advocate that children are expected to move through a series of locomotor patterns which reflect earlier forms of movements that human evolutionary ancestors performed, such as creeping and crawling. As such, skipping one of these evolutionary steps in one’s own development is believed to result in perceptual and motor difficulty as well as disturbances in language and communication skills (Doman 1974). The method presumes that basic motor sequences are essential to the neurological organization of an individual. According to the authors, the different stages of crawling, creeping, and walking are each associated with a unique neurological function and a gap in the appropriate sequence does not allow for an individual to fully develop (Doman 1964b). For example, a child who failed to crawl before walking is hypothesized to have skipped a critical step unique to human development, and this gap leaves the child subjected to both higher and lower order neurological deficits. Based on this rationale, it follows that the child must be “patterned” by a team of adults trained to position the child’s body in such a way that mimics this critical prerequisite step. As a result, the child’s neurons would be “repatterned” and reorganized in a way that allows them to continue with their typical development and encourage learning readiness in academic skills. According to this theory, intellectual disabilities, learning, and behavior disorders are caused by brain damage. Most importantly, these deficiencies are believed to exist on a single continuum for which the only solution is to regress to earlier forms of primitive movement (Cohen et al. 1970).

On the phylogenetic continuum, human movement may be divided into five main classes:

1. Truncal movement: Comparable to the swimming movement of a fish and believed to impact the medullary level of the brain.

2. Homolateral crawling: Defined as a crawling motion in which the arm and leg on the side to which the head is turned and flexed, while the opposite extremities are extended. This is hypothesized to reflect amphibian motility and believed to affect a pontine level of brain organization.
3. Cross-pattern creeping: Defined as creeping with a flexed arm and extended leg on the side toward which the head is turned. This creeping is believed to be related to reptilian movement and is hypothesized to be related to midbrain functioning.
4. Crude walking: Defined as walking without a cross pattern. This reflects a primitive upright form of locomotion consistent with cortical functioning.
5. Cross-pattern walking: Defined as the only uniquely human gait and associated with advanced cerebral function and hemispheric dominance.

In addition, the importance of establishing cerebral dominance is believed to be unique to humans, and this lateral neurological function is said to account for the human ability to read, write, and talk. As such, the lateralization of movement is central in the theory and practice of this method (Holm 1983). The authors also emphasize the importance of adding ongoing sensory stimulation to the patterning movements, as learning begins with the stimulation of the senses.

Goals and Objectives

Treatment goals of the Doman-Delacato method aim to improve physical, intellectual, and social capability in children with brain injuries by correcting “neurological organization.”

Treatment Participants

Proponents of the method believe that treatment is suitable for all children classified as “brain-injured.” As defined by the IAHP, the term “brain-injured” encompasses nearly 300 potential

childhood disorders. The IAHP does not differentiate across severity, and even the most severely handicapped children may be admitted. Doman and Delacato have repeatedly emphasized that only those parents who are most dedicated to their children’s recovery can expect to see a result from the prescribed demanding regimen.

Treatment Procedures

Predetermined patterns of movement are imposed on the child by manipulation of the child’s extremities. Such manipulations are performed by teams of up to five people, often consisting of therapists, parents, and volunteers. In the sessions, each adult is responsible for manipulating one of the child’s limbs or the head. It is required that it should be performed smoothly and rhythmically and in complete accordance with the movement of the other limbs in order to mimic the natural movement of the body (Doman et al. 1960). The IAHP recommends that these exercises be conducted a minimum of at least 5 min, four times a day every day of the week. While the treatment team is initially composed of therapists, it gradually becomes the responsibility of parents and volunteers to conduct the sessions. Typically, the treatment therapists conduct follow-up visits in 60- to 90-day intervals. It is hypothesized that such patterning sessions will ingrain the movements into the central nervous system.

Parents are also required to provide their children with a program of sensory stimulation. In addition, masking, or rebreathing expired air into a face mask for 30 to 60 s once every waking hour, is promoted to increase cerebral blood flow, increase carbon dioxide intake, and aid in the establishment of hemispheric dominance (Freeman 1967). According to the IAHP, this rebreathing treatment is also recommended in the treatment of seizure disorders, and the IAHP requires that all patients be gradually weaned off of anticonvulsant medications to maximize the effectiveness of their own treatment regimen. Restricting salt, sugar, and fluids and limiting exposure to music are additional recommendations.

Efficacy Information

The Doman-Delacato method has not been scientifically investigated with individuals on the autism spectrum. To date, the concept of neurological organization that serves as the foundation for the method has not been subjected to scientific research, and those programs which offer patterning have not been shown to improved learning or functioning. Many have contested that the theoretical rationale for the treatment is without merit and is inconsistent with accepted views of neurologic development (Novella 1996). Although any intervention that calls for one-to-one daily interaction for hours at a time on a daily basis might have the potential to have some positive effect, evidence for any permanent and lasting change from patterning is lacking (Howlin 1997). As a result, this method has been met with controversy and criticism.

The American Academy of Pediatrics Committee on Children with Disabilities has issued several cautionary statements regarding the Doman-Delacato method. Due to the lack of empirical support for the strategies, warnings were published as early as 1968, with the most recent statement reaffirmed in 2005 (American Academy of Pediatrics 1982; 1999). This was a joint statement approved by several organizations, including but not limited to the American Academy for Cerebral Palsy, American Academy of Neurology, American Academy for Physical Medicine and Rehabilitation, American Academy of Orthopedics, Canadian Association for Retarded Children, and the National Association for Retarded Citizens (Hyatt 2007).

Outcome Measurement

The primary outcome measurement tool for this therapy was developed by the inventors of this method. The Doman-Delacato developmental profile, which is used for both planning treatment and monitoring progress, enables the therapist to ascertain at which level of neurological organization a brain-injured child is functioning. The profile is based on chronological age development

when the following domains are hypothesized to develop mobility, language, manual competence (writing), vision (reading), auditory competence, and tactile competence. Each of these domains is divided into seven chronological stages of functional development which corresponds with ascending brain levels.

The validity of this tool for planning treatment or measuring outcome has yet to be demonstrated (Sparrow and Zigler 1978). Because the administration of this instrument at intake informs the course of treatment, changes with treatment may reflect teaching to the test and do not necessarily correlate with a generalizable improvement in functioning. To date, this measurement has not been standardized against any accepted measures of development, although inter-rater reliability is reported to be valid. The dimensions measured by the assessment make the comparison to any standard measure difficult.

Qualifications of Treatment Providers

Staff at the IAHP are trained as “child brain developmentalists.” These developmentalists specialize in one of the following: intellectual excellence, physical excellence, or physiological excellence. According to IAHP literature, this certification requires rigorous training and yearly recertification. No certification or licensure process exists outside of the Institutes for the Achievement of Human Potential, and the required qualifications of these child brain developmentalists are not publically disclosed. The IAHP continually holds courses in seminars throughout the world to educate parents on how to conduct patterning with their children.

PDD-NOS (Pervasive Developmental Disorder Not Otherwise Specified)

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

The equivalent, if somewhat ambiguous, terms PDD-NOS, "subthreshold" autism, and "atypical" autism refer to the broad range of conditions characterized by problems in social communication as well as in communication and/or restricted interests and behaviors that are suggestive of more strictly defined autism but fall short of the latter concept in terms of symptom thresholds. This term was used in DSM-II-R and DSM-IV and would be somewhat analogous to the term "broader autism phenotype." DSM-5 did not include this term, and most cases with it (under ► "DSM-IV") would no longer receive a diagnosis (McPartland et al. 2012), but such cases, if they had a "well-established" diagnosis before DSM-5, were "grandfathered" in.

Historical Background

The concept has, in many respects, its origins in Rank's use of the term atypical personality development to describe a range of difficulties in social-

emotional development and regulation (Rank 1949; Caplan 1955). In DSM-III (1980), the word atypical was used to describe “subthreshold” autism as the latter diagnosis was included in the PDD class for the first time as an official diagnosis. This use of the term unintentionally hearkened back to Rank’s earlier use of the same word you describe a rather similar diagnostic concept. In recent years, an awareness of the “broader autism phenotype” and the complex genetics surrounding autism have lent increased interest to work on this concept (Towbin 2005; Towbin et al. 2005) which clearly outnumbered more classical autism (Fombonne 2005).

Current Knowledge

At present, this and related terms refer to a “residual” category included in DSM and ICD for individuals whose problems do not meet the threshold for diagnosis but which are sufficiently severe as to serve as a source of impairment/distress and are relevant focus for treatment. In reality, the term refers to a relatively large group (probably about 1 in 150 children) of children. Clearly, there is even greater heterogeneity within this condition than there is with autism. Understandably, many attempts have been made to define specific subgroups/subtypes, e.g., individuals with greater intentional difficulties versus those with more mood/affective problems (Hellgren et al. 1994; Landgren et al. 1996). Study of the condition may be particularly relevant to the delineation of specific genetic mechanisms (Rutter 2005; Towbin et al. 2005).

In terms of clinical presentation, individuals with this condition frequently exhibit social difficulties, emotional lability, and unusual sensitivities, although, as a group, they probably have cognitive and language abilities than in more “classical” autism. Frequently, clinicians equate the concept with Asperger’s disorder, although some data suggest that in the latter condition social deficits are more severe (Klin et al. 2005; Volkmar et al. 1994; Volkmar and Klin 2000). Treatment approaches are rather similar to those for autism but with an awareness of often reasonably good cognitive potential and the presence of

comorbid conditions like anxiety and mood problems as well as affective lability (Towbin 2005). As noted above the lack of explicit recognition in DSM-5 is problematic.

Future Directions

Over the coming years, the identification of specific genetic subgroups/subtypes of autism will likely lead to a refinement of this concept.

Peabody Developmental Motor Scales (PDMS)

Renee Watling

Division of Occupational Therapy, Department of Rehabilitation Medicine, University of Washington, Seattle, WA, USA

Synonyms

[PDMS](#); [PDMS-II](#); [PDMS-2](#)

Description

The Peabody Developmental Motor Scales-2 (PDMS-2; Folio and Fewell 2000) is a criterion-referenced and norm-referenced developmental assessment comprised of two scales: the Gross Motor Scale and the Fine Motor Scale. The Gross Motor Scale includes four categories: reflexes, stationary gross motor skills, locomotion, and object manipulation. The reflex subtest is administered to children from birth through 11 months. It contains eight items that measure reactions to environmental events. The stationary subtest includes 30 items that measure equilibrium and sustained control of the body within the center of gravity. The locomotion subtest measures the child's skills in moving from one place to another through 89 items that cover the developmental progression of various modes of movement. The object manipulation subtest includes 24 items that measure the ability to manipulate balls. Test items specifically measure skills such as:

- Reflex integration and postural adjustments
- Balancing on one foot and on tiptoes
- Crawling, walking, running, jumping, and skipping
- Throwing, catching, and kicking a ball

The Fine Motor Scale is comprised of two categories: grasping and visual-motor integration. The grasping subtest includes 26 items that

measure the ability of the child to use hands independently or together. The visual-motor integration subtest contains 72 items that measure visual perceptual skills and eye-hand coordination. Test items specifically measure skills such as:

- Demonstrating various grasp patterns as appropriate for different objects
- Stacking or configuring blocks to replicate a demonstrated design
- Manipulating buttons, using scissors, folding paper, and drawing to copy designs

A child's performance on each test item is scored a 0, 1, or 2. A score of 0 indicates no success on the item, 1 indicates emerging abilities to complete the item, and 2 indicates mastery or success in meeting all criteria for the test item. Test scores can be calculated as percentiles, standard scores, and age equivalents for the Gross Motor Quotient, Fine Motor Quotient, and Total Motor Quotient.

As a performance-based measure, the PDMS-2 can be administered in approximately 20–30 min per scale and 45–60 min for the total test (Folio and Fewell 2000).

Historical Background

The Peabody Developmental Motor Scales (PDMS; Folio and Fewell 1983), originally published in 1983, consisted of a Gross Motor Scale and Fine Motor Scale which were normed for children ages 1–83 months. The scales could be used separately to measure the respective motor domain or used together to obtain an overall motor performance composite score. The test was widely used throughout North America and frequently referenced in the published literature. The PDMS was revised in the late 1990s in order to update test items and establish contemporary norms. Normative data were collected between 1997 and 1998 using a sample of 2,003 North American children representing four major geographic regions from 46 states and one Canadian province. The test continues to be widely used by occupational and physical therapists and can also

be administered by diagnosticians, early intervention specialists, psychologists, and others with training in motor skill assessment.

Psychometric Data

Characteristics of the normative sample for the PDMS-2 were consistent with the 1997 US Census demographic data with respect to geographical area, gender, race, residence location (rural, suburban, urban), ethnicity, and socioeconomic status. Overall, the sample is considered representative of the US population at the time the test was developed. Scoring norms are available for typically developing children from birth through age 5 (1–84 months). No normative data are available for children with disability conditions.

Reliability. Internal consistency was evaluated using Cronbach's coefficient alphas. Values ranged from 0.84 to 0.98 indicating strong associations among test items within the same construct (e.g., fine motor, gross motor). Measures of test-retest reliability were limited to two groups of young children ages 2 through 11 months ($n = 20$) and 12 through 17 months ($n = 30$). Resulting correlation coefficients ranged from 0.73 to 0.96, suggesting acceptable test-retest reliability within the items applicable to these age groups. Inter-rater reliability for test scores yielded coefficient values of 0.96 to 0.98. Inter-rater reliability for individual test items has not been examined.

Validity. Content validity of the PDMS-2 is supported through developmental theory and various item analysis techniques including item response theory and logistic regression. Age-related trends, such as increases in mean test scores occurring with increasing age, have been observed. The various subtests within each composite are supported through confirmatory factor analysis. Concurrent validity was examined between the PDMS-2 and the initial version of the test, the PDMS. The resulting correlations were strong with 0.84 for the fine motor composite and 0.91 for the gross motor composite. Moderate to strong correlations were also noted with

scores from the gross and fine motor scales of the Mullen Scales of Early Learning: AGS Edition.

Clinical Uses

The PDMS-2 is often used in clinical and educational settings to assess gross and fine motor skills along the developmental trajectory (Richardson 2010). The tool can be used to identify children with delays in motor skills and to plan intervention.

Peabody Individual Achievement Test, Revised

Melissa Maye

Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Synonyms

PIAT-R; PIAT-R/NU

Description

The PIAT-R/NU assesses achievement across six different content areas: general information, reading recognition, reading comprehension, mathematics, spelling, and written expression. The PIAT-R/NU does not consolidate each content area under a specific domain, and only the subtests that contain content related to the individual's educational concern should be administered. However, in order to calculate composite scores, multiple tests must be administered. The administration of multiple tests allows for a more in-depth understanding of an individual's strengths and weaknesses. The PIAT-R/NU allows for composite scores to be derived from the reading (Total Reading) and writing (Written Language) subtests. A total composite score (Total Test) can also be calculated utilizing five of the six subtests (excludes Written Expression). The PIAT-R/NU is published by Pearson Assessments and the author is Frederick C. Markwardt, Jr.

The General Information subtest contains 100 items that assess general knowledge. The topics included within this subtest are: science, social studies, fine arts, and factual knowledge. These items are administered verbally. The Reading Recognition subtest contains 100 items that measure recognition of printed letters and assess an individual's ability to read words out loud. These items also require a verbal response. The Reading Comprehension subtest consists of 82 items that measure reading comprehension. This task necessitates an individual to be able to

select a picture (by pointing or verbal response) that best illustrates a sentence that she/he has just read. The Mathematics subtest contains 100 questions. In this subtest, an individual is read a math question and then is required to respond via multiple choice either orally, or by pointing. The Spelling subtest consists of 100 items that assess both letter recognition (both by name and by sound) and spelling words correctly. The spelling portion of this subtest requires the examinee to choose the correctly spelled word from a choice of several words, either verbally or by pointing. The Written Expression subtest assesses both prewriting skills (i.e., the ability to copy and write letters, words, and sentences from dictation) and the ability to write a story about a presented picture (Sattler 2001).

Criticisms of the PIAT-R/NU include that the Reading Comprehension subtest may be more of an assessment of memory, as opposed to reading comprehension. The Mathematics subtest does not include any paper and pencil computations and covers a large range of mathematical skills and therefore does not narrow in on any one topic. The format of the spelling test (choosing from a group of variations of the target word) may not adequately assess for spelling ability. Lastly, the Written Expression subtest has low test-retest reliabilities, inter-scorer reliabilities, and internal consistency reliabilities (Sattler 2001).

A score of "1" indicates a correct score and a score of "0" indicates an incorrect score, with the exception of Written Expression. Raw scores are converted to standardized scores, grade equivalents, age-equivalent scores, percentile ranks, normal curve equivalents, and stanine scores. The Written Expression subtest requires a general achievement score to be calculated, and then grade-based stanines and a developmental scaled score are provided (Sattler 2001).

Scoring software is available to decrease the amount of time spent scoring and increase accuracy. The software is available for both Windows and Macintosh operating systems. The scoring software also allows reports to be generated in both English and Spanish.

In addition to being used with typically developing children, the PIAT-R/NU is an adequate

assessment tool for individuals with developmental difficulties such as intellectual disability. Furthermore, the PIAT-R/NU can be a useful tool for children with Autism Spectrum Disorders (ASDs) given the flexibility of the instrument. Individuals with an ASD often have varied needs across the spectrum resulting in atypical testing approaches being a necessary component of a quality assessment (Koegel et al. 1997). The PIAT-R/NU allows for this flexibility with six subtests that can be used interchangeably in response to an individual's needs and/or a spoiled administration of a subtest. Additionally, many of the subtests allow for responses in a multiple choice approach. For example, the mathematics subtest requires the examiner to read a question out loud and then the individual chooses the best answer from a limited selection. Other subtests allow for responses to be counted if they are gestured, written, or spoken. This format is especially useful for testing individuals with adequate receptive and low expressive language abilities, which often describe individuals with an ASD (Sattler 2001).

Historical Background

The Peabody Individual Achievement Test (PIAT) was first published in 1970 by Llyod Dunn and Frederick C. Markwardt, Jr. The original version of the achievement test only contained five subtests. When the PIAT was re-normed in 1989 the subtest Written Expression was added, thus resulting in the Peabody Individual Achievement Test, Revised (PIAT-R). In addition to the creation of a new subtest, most of the items of the original five subtests were replaced with new items to address changes in school curriculum (Allinder and Fuchs 1992). The PIAT-R was then re-normed between 1995 and 1996 as a part of a coordinated norming initiative, thus resulting in the Peabody Individual Achievement Test, Revised/Norms Update (PIAT-R/NU). The re-norming process allowed for an extension of the age range from 22-years-0-months to 22-years-11-months. The PIAT-R/NU is the most up-to-date version of the test.

Psychometric Data

The PIAT-R/NU was standardized between 1995 and 1996 as part of a re-norming project that included the KeyMath-Revised, Kaufman Test of Educational Achievement-Brief Edition, Kaufman Test of Educational Achievement-Comprehensive Edition, and Woodcock Reading Mastery Tests-Revised. The sample that the PIAT-R/NU was standardized with included 3184 children between the grades of kindergarten and the 12th grade and 245 young adults between the ages of 18 and 22. Between 204 and 295 children were administered each subtest per grade level. Special needs populations were included in the standardization process consistent with the nationwide representation. The sample is representative of 40 of the 52 states of the United States of America (USA). The sample was representative of the 1994 US census data with respect to gender, race/ethnicity, parental education, educational placement and geographic region. Most children did not receive the complete PIAT-R during the norming process (Sattler 2001).

For five of the six subtests, internal consistency reliabilities were quite good ranging from .87 to .98. For the Written Expression subtest, internal consistency reliability ranged from .60 to .91, relatively weaker in comparison to the other subtests (Sattler 2001).

Test-retest reliability was acceptable with correlations ranging in the high .80s to the mid-.90s for grade norms and with correlations ranging in the low to mid-.90s for age norms. Inter-rater reliability was low for Written Expression with Level II reliability being .58 for Prompt A and .69 for Prompt B.

The validity of the PIAT-R/NU is considered acceptable. The clinical validity studies completed have suggested that the PIAT-R/NU is a sensitive tool used to distinguish strengths and weaknesses across five of the six subtests.

Clinical Uses

Achievement testing is a necessary component of any special needs assessment protocol. Utilizing a measure, like the PIAT-R/NU, that allows for

broad screening and is adaptive and flexible allows for easing the challenges of testing individuals who are restricted verbally. Achievement testing allows for better Individual Education Plans (IEPs) to be developed that are specific to the needs of the student. Without the use of achievement testing IEPs risk being broad and nonspecific to the individual student, thus running the risk of not receiving adequate services and school placement.

The PIAT-R/NU is advantageous in that there are norms for both grade level and age. This allows for nontraditional students to be assessed and compared on multiple levels. For example, if a student with mild intellectual disability was held back a year and was being assessed to determine grade placement for the following year, it would be useful to consult the grade norms as opposed to the age norms to determine advancement.

Not only can the PIAT-R/NU be helpful in the school setting to aid in assessing strengths and weaknesses and creating goals for IEPs, but they also can assist in procuring services such as need-based tutoring, special education placement, and Title I services.

Appropriate intervention following a screen demonstrating academic weaknesses could result in significant gains for many individuals. The PIAT-R/NU is unique in that it allows for even individuals with low expressive language to be evaluated which offers many opportunities for helping these individuals work on building both their strengths and weaknesses.

Peabody Picture Vocabulary Test

Inge-Marie Eigsti
Department of Psychological Sciences,
University of Connecticut, Storrs, CT, USA

Synonyms

Peabody Picture Vocabulary Test, Fourth Edition (PPVT)

Description

The PPVT is a test of receptive vocabulary – that is, it assesses the lexicon of words that a person can understand when he or she hears them. It is also designed to serve as a screening test for verbal ability. The test has a straightforward structure. Examinees see a page on an easel with four-color pictures. For each item, the examiner says a word, and the examinee responds by selecting one picture out of four that best illustrates that word's meaning. Because the examinee points to the appropriate item, the test requires no reading, writing, or expressive verbal language, and it can be used with nonreaders and those without fluent verbal abilities. The test is untimed and individually administered. In total, the PPVT contains 228 items, divided into 19 “sets” of 12 items each; an examinee completes all items within a set. The *basal* level is set when an examinee correctly responds to 11 or more items in a set; the *ceiling* is established as the set where an examinee makes eight or more errors. Basal and ceiling levels are thought to represent the levels of difficulty below which an examinee is expected to know all items and above which the examinee is predicted to fail most items, respectively.

The PPVT was conformed with the Expressive Vocabulary Test – Second Edition, which serves as a measure of what words a person can speak aloud after seeing a pictorial representation of the item; PPVT and EVT scores were correlated at $r(3540) = 0.82$ in the normative sample. PPVT

scores are provided as standard scores with a mean of 100 and a standard deviation of 15. Grade- and age-equivalent scores can also be computed and can help with interpreting an examinee's relative knowledge. However, such scores are not recommended for research use given discontinuities between months or grades; that is, there are meaningful differences in the rate of development over different age periods, or between grade levels, which makes the steps between levels noncontinuous. Furthermore, consumers of such scores may not always remember that, as an average score, there must by necessity be 50% of examinees that score below the mean for a given age or grade level. Finally, users can also calculate a growth scale value, which tracks vocabulary over time.

Historical Background

The first edition of the PPVT was published by Lloyd M. Dunn in 1959. Subsequent revisions were published by Lloyd and Leota Dunn in 1981 (PPVT-R), in 1997 (PPVT-III), and by Douglas Dunn (son of Lloyd and Leota, Ph.D.) in (2007) The PPVT-4 is the current version. Lloyd Dunn, an expert in the fields of special education and child development, founded the Kennedy Center in 1965 and was central in efforts to train researchers in the field of mental retardation. His early work was instrumental in promoting *educational mainstreaming* and, more generally, addressing the educational needs of children whose abilities differ from the average. He served as the first director of the Institute on Mental Retardation and Intellectual Development, an institute of the Kennedy Center, developed the first doctoral program in special education at the Vanderbilt Peabody College of Education and Human Development, and developed a number of tools designed to assess language and cognitive skills in the service of educational intervention.

Recently, the PPVT-4 was incorporated into the NIH Toolbox – Cognition Battery (Gershon et al. 2014), based on its high test–retest reliability and strong construct validity when compared with relevant gold-standard measures. The NIH

Toolbox provides a battery of very brief measures designed to assess core functions (cognitive, emotional, sensory, and motor processes) using an iPad, with the guidance of an experimenter.

Psychometric Data

Words for the PPVT were originally selected from the dictionary on the basis of their imageability; the target word and the three distractors all had to be amenable to representation via line drawings (originally in black and white, all items are now depicted in color; all can be distinguished by color-blind individuals). Items were selected from the categories of body parts, emotions, foods, clothing, toys and recreation, and so on. In earlier versions of the test, there was a high proportion of items depicting verbs, but the PPVT-4 contains a smaller proportion of these items; they were found to be disproportionately difficult for young children. All items in a given trial are balanced for detail and visual complexity. There are four training items, for which the examiner is permitted to give feedback. An examinee must correctly complete two of these items in order for testing to be valid. The training items permit the examiner to establish whether the examinee is capable of responding in a standard fashion.

The PPVT-4 was standardized on a sample of 3540 individuals between the ages of 2 years, 6 months, and 90 years. Participants were representative of the general US population (according to census data) in terms of gender (male, female), ethnicity (Latino/Latina/Hispanic, African American, White, and "other," a group comprising American Indians, Alaska Natives, Asian Americans, Pacific Islanders, and all other groups not otherwise classified), geographic region, socioeconomic status, and special education placement. Twelve percent of the sample had parents whose educational achievement was grade 11 or lower; 28% had achieved 12th grade or a GED; 31% had 1–3 years of college; and 28% had 4 or more years of college. To establish age norms, the sample consisted of 28 age groups, with approximately 100–200 cases in each group; for ages

2–6 years, intervals were 6 months to account for the rapidly changing vocabulary levels in young children. All other groups were stratified by year. Fifty-seven percent ($n = 2003$) of the sample also contributed to a grade-stratified sample, comprising 26 groups (fall and spring, kindergarten through twelfth grade).

In addition, some participants in the normative sample had developmental concerns: speech or language impairment (5–15 years, $n = 178$ for ages 5–15; $n = 60$ ages 50–96), language delay (3–7 years, $n = 63$), intellectual disability (6–17 years, $n = 70$), reading disability (ages 8–14 years, $n = 71$), ADHD (6–17 years, $n = 91$), hearing impairment (4–12 years, $n = 99$), and several low-incidence disabilities. ASD was not specifically targeted. Proportions of special populations were intended to match population percentages. Data for average scores for these subgroups relative to the larger reference group are provided in the technical manual and range from a relatively small difference of -5.6 points for individuals with speech impairment to a relatively large difference of -29.7 points for hearing-impaired individuals with cochlear implants.

Two alternate forms are available, providing the option to repeat assessments more frequently. The reliability of these forms, which are identical in format and organization, with parallel but non-identical words tested, was assessed at 0.94. This permits the PPVT to serve as an assessment of *response to intervention* and for other methods requiring multiple test administrations. Test-retest correlations range from 0.92 to 0.96.

Construct validity of the PPVT-4 was assessed using the Comprehensive Assessment of Spoken Language (CASL; Carrow-Woolfolk 1999); for ages 3–5 years ($n = 68$), CASL subtest scores correlated with the PPVT as follows: basic concepts, $r = 0.50$; antonyms, $r = 0.41$; and sentence completion, $r = 0.54$. For ages 8–12 years ($n = 62$), CASL subtest scores correlated with the PPVT as follows: synonyms, $r = 0.65$; antonyms, $r = 0.78$; sentence completion, $r = 0.63$; and lexical/semantic composite, $r = 0.79$. Correlations with core language scores from Clinical Evaluation of Language Fundamentals –

Fourth Edition ranged from 0.73 (ages 5–8) to 0.72 (ages 9–12), with slightly lower correlations for the receptive ($r = 0.67$ and 0.75 for the two age groups) and expressive ($r = 0.75$ and 0.86 for the two age groups) subscales. These moderate-to-high correlations indicate that the other oral language assessments measure a constellation of similar but nonidentical skills. The PPVT-4 test is reliable, with all reliability and validity coefficients in the .90s range.

Clinical Uses

Research partially supports the utility of the PPVT as an assessment of general language abilities in the autism spectrum disorders. A study of 44 children with autism, ages 4–14, found that standardized measures of language ability (PPVT, EVT, and Clinical Evaluation of Language Fundamentals) correlated well with spontaneous assessments (mean length of utterance, index of productive syntax, and number of different word roots; Condouris et al. 2003). Furthermore, the assessments of vocabulary and semantic knowledge more generally were significantly correlated with assessments of grammatical knowledge. A meta-analysis of 133 publications in the field of ASD between 1999 and 2002 (Mottron 2004) found that a vocabulary measure (British Picture Vocabulary Scale, or BPVS; nearly identical in structure to the PPVT) had been used as a matching variable for 22% of publications, second only to overall IQ estimations using the Wechsler scales (47%). Thus, research in the field has acted in accord with the assumption that vocabulary skills, estimated with the PPVT, may be a useful proxy for general verbal language skills. Certainly, data from typical development indicates that vocabulary correlates highly with other language abilities and is the single best predictor of academic success for children starting school.

However, there is significant evidence that vocabulary assessed by the PPVT may be a strength for individuals with ASD relative to morphosyntax (Eigsti et al. 2007) or discourse-level comprehension (Asberg 2011). That is,

PPVT scores may overestimate general verbal abilities. Supporting this proposal, Mottron (2004) reported that receptive vocabulary may be a particular area of strength in ASD, even compared to tests considered to tap into ASD-specific expertise, such as block design tasks. Thus, vocabulary skills, estimated with the PPVT, may overestimate the functional abilities of participants with ASD.

The PPVT-4 has several specific limitations. First, it assesses only vocabulary items that are imageable – primarily, concrete nouns and verbs. As noted above, verbs, function words (*and*, *if*), and grammatical markers (*-ing*, plural “*s*”) are absent from the test. Thus, if an individual has a specific deficit in morphosyntactic abilities, the PPVT will fail to identify this difficulty. Second, the PPVT is inadequate for assessing individuals who are not fluent in English. There is also a Spanish version (Test de Vocabulario en Imagenes, TVIP; 1986) whose format is similar to the English version but with distinct items; because word frequencies differ dramatically across languages, it is not possible to simply translate items into another language (see an example of the challenge in a Danish study; Brynskov et al. 2017).

A third important limitation of the PPVT, specific to the case of ASD, is the presence of atypical vocabulary skills, such as the production of jargon words or echolalia (Eigsti et al. 2007). Children with ASD have been found to show some similar word-learning biases to typically developing children, in that they are able to map novel words onto novel objects, suggesting that their word learning is constrained by a “mutual exclusivity” bias that category labels apply to mutually exclusive objects (de Marchena et al. 2011). Furthermore, they are able to sort objects according to typical semantic categories. In contrast, research suggests that individuals with ASD produce less prototypical words, have difficulty in learning words that refer to mental states, and show differential priming effects (as reviewed in Eigsti et al. 2011); they also fail to show the developmentally typical shape bias (Tek et al. 2008). Because the PPVT is organized according to how vocabularies are structured in typically developing individuals, it may fail to

detect differences in ASD. This lack of sensitivity is further possible because the PPVT does not have any overt semantic organization in the scoring procedure; it is not possible to report a particular deficit in acquisition of words in any particular semantic (or structural) language category.

One final topic bears explicit mention. Clinicians have occasionally reported better responses by individuals with ASD in the PPVT when assessed using facilitated communication strategies. However, studies explicitly comparing responses by examinees with the assistance of facilitators who could or could not see the task materials have conclusively demonstrated that any improvement in scores using assistance primarily reflects the facilitator rather than the examinee's knowledge (Beck and Pirovano 1996).

Description

The Promoting the Emergence of Advanced Knowledge (PEAK) relational training system is a criterion referenced assessment and curriculum designed to provide a measure of an individual's language and verbal abilities. The PEAK relational training system is composed of four separate modules: PEAK-Direct Training (PEAK-DT; Dixon 2014a), PEAK-Generalization (PEAK-G; Dixon 2014b), PEAK-Equivalence (PEAK-E; Dixon 2015), and PEAK-Transformation (PEAK-T; Dixon 2016). Each module contains a 184-item assessment designed to identify language skills present within an individual's repertoire and potential skill deficits the individual is lacking. Scores on the assessment are representative of an individual's current verbal abilities, in which a lower score on the assessment is indicative having a limited verbal repertoire, whereas higher scores are indicative of having a more complex verbal repertoire. Because procedures for conducting the assessments vary slightly for each module, each contains specific instructions for conducting the assessments for that specific module. Also contained within each module is a curriculum containing 184-programs that correspond to each of the items from the assessment. The programs aim to teach any of the skill deficits identified as lacking indicated by results from the assessment. Each program sheet contains a goal statement for the targeted skill, a material list, instructions for teaching the skill, and example stimuli typically utilized during instruction for that particular program. Although the modules advance in complexity with the PEAK-DT module being the least complex and the PEAK-T being the most complex, it is intended for program instruction of the four modules to be conducted simultaneously. Program instruction for all for modules is conducted using discrete trial training

(DTT) format. In this format, instruction consists of clearly defined units that allow for the delivery of a task or question issued to the learner, followed by specific feedback for the response to that particular task/question. Following the delivery of the task/question, the implementor waits for the learner to emit a response and provides a reinforcer or reward for correct responses and corrective feedback through the use of prompts or modeling for incorrect responses. Because each response contacts some type of consequence, the learner's responding will be modified accordingly. As individuals acquire the targeted skills necessary for program mastery, more advanced programs are then introduced, which allow for more complex language and verbal skills to be targeted.

The first two modules, the PEAK-DT module (Dixon 2014a) and the PEAK-G module (Dixon 2014b), share similarities in terms of assessment administration and program implementation. Items on the PEAK-DT and PEAK-G modules can be conducted using either an indirect or direct assessment. For indirect assessment administration, the assessor simply reviews each item on the assessment and indicates whether the individual has been observed to engage in the targeted skill previously or not. If the individual has the skill in their repertoire, then the assessor marks the item as "Yes" on the assessment scoring sheet. If the individual has not been observed as engaging in the targeted skill, then the assessor marks the item as "No" on the assessment scoring sheet. If the assessor is unsure whether the individual has the targeted skill in their repertoire, then the assessor marks the item as "?" on the assessment scoring sheet. All items marked as "?" on the scoring sheet will be directly assessed subsequently. To conduct a direct assessment, the assessor systematically presents each item to an individual and records whether they engage in the targeted skill. The assessor marks "Yes" on the assessment scoring sheet if the individual engages in the targeted skill and "No" if the individual does not respond or engages in an incorrect form of the targeted behavior. Although both indirect and direct assessment methods can be utilized to identify potential skill deficits, the authors recommend

direct assessment over indirect assessment, as this allows for more accurate assessment results. Regarding program implementation, both the PEAK-DT and PEAK-G modules focus on contingency-based learning approaches to teaching language and verbal skills. Many of the first programs in the PEAK-DT module focus on establishing basic prerequisite skills necessary for program instruction to take place (e.g., eye contact, turn-taking, and following instructions) or focus on simpler, basic language and verbal skills (e.g., oral motor imitation, making requests using yes and no, and vocal imitation). Later programs build upon earlier programs and target more complex language and verbal skills (e.g., receptive and expressive identification of stimuli, demonstrating adverb action, and guessing). Program instruction for the PEAK-DT module is conducted using DTT procedures, in which every response is followed by feedback. Similarly, programs within the PEAK-G also increase in complexity as an individual progresses through the programs. There are, however, differences in terms of program implementation. The PEAK-G module differs from the PEAK-DT module in that it incorporates a train-test methodology for program instruction. This methodology involves presenting untrained stimuli that are embedded within blocks of directly trained stimuli, in order to promote stimulus and response generalization.

The last two modules, PEAK-E module (Dixon 2015) and the PEAK-T module (Dixon 2016), move beyond the other modules to promote derived responding similar to that commonly exhibited in deductive and inductive reasoning tasks. Assessment administration of these two modules differs slightly than that of the previously mentioned modules, in that these modules incorporate the use of a pre-assessment. The pre-assessment is brief assessment designed to provide an initial evaluation of an individual's complex language and verbal abilities. Scores on the pre-assessment are then used to determine a starting point of the full assessments for the corresponding modules. The PEAK-E pre-assessment consists of a single 48-item assessment that requires both receptive and expressive responses from the learner. The PEAK-T module

pre-assessment consists of a 96-item receptive assessment and a 96-item expressive assessment, which are conducted separately from one another. The PEAK-E and PEAK-T full assessments are divided into different levels of complexity, with the least complex levels occurring near the beginning of the assessment and the most complex levels occurring toward the end of the assessment. Higher scores on the pre-assessment are indicative of an individual having more complex language and verbal skills and lower scores indicative of lower language and verbal skills. Therefore, higher scores on the pre-assessment mean an assessor will start the full assessment at a higher level, and for lower scores the assessor will begin at a lower level. Regarding program implementation, although some discrepancies exist between the two modules, the general method for program implementation is similar. Program implementation involves teaching a specific set of stimulus relations while testing another set of stimulus relations to evaluate the extent to which individuals infer the untrained stimulus relations. The PEAK-E and PEAK-T modules are designed to promote the emergence of complex verbal and deductive reasoning skills so that they occur naturally without direct training and facilitate this pattern of responding as it applies to a larger societal context.

Historical Background

The first two PEAK books, the PEAK-DT and PEAK-G modules, were published in 2014, followed by the PEAK-E module in 2015 and the PEAK-T module in 2016. All modules are in their first editions; however, analyses have been conducted to evaluate the underlying constructs of the programs within the modules. Principal component analyses were conducted for the PEAK-DT module (Rowsey et al. 2015) and the PEAK-G module (Rowsey et al. 2017). The principal component analyses provided information regarding the internal consistency of the modules and allowed the developers to categorize programs into specific components and arrange programs in order of their complexity.

Psychometric Data

Since the PEAK relational training system first emerged in 2014, data has been generated regarding the psychometric properties of the system. A majority of studies examining psychometric properties of the PEAK system were conducted on the PEAK-DT and PEAK-G modules. Psychometric data for the PEAK-E and PEAK-T exists but is limited, due to these modules being the most recently published of the series.

In terms of reliability, several studies have been conducted that assessed the reliability of the PEAK relational training system. Dixon, Stanley, Belisle, and Rowsey (2016) evaluated the test-retest reliability of the PEAK-DT module. In this study involving 39 participants (ages 6–20), the authors administered the PEAK-DT assessment on two separate occasions, during an initial assessment and during a follow-up assessment 3 weeks to 1 month later. The results suggested the PEAK-DT module had high test-retest reliability (intraclass correlation = 0.987, $p < 0.001$). Test-retest reliability has not been evaluated on the other modules in the PEAK relational training system. Another form of reliability that has been evaluated is inter-rater reliability (IRR). In addition to evaluating test-retest reliability, Dixon et al. (2016) also evaluated inter-rater reliability with a subset of ten participants in their study. To accomplish this, a second assessor scored assessments for the subset of participants, and these scores were then compared to the assessment scores of the primary assessor. Both assessors were blind to the other assessors' scores. IRR was assessed by determining the percentage of items in which the two observers scored an assessment item the same. The IRR analyses revealed a strong relationship between the two assessors scores, with a Cohen's kappa reliability coefficient of 0.981 ($p < 0.001$) and total agreement score of 99%. Several other studies have reported IRR for the PEAK-DT module. For example, McKeel et al. (2015b) evaluated IRR for a small portion of participants in their study ($n = 8$; ages 2–22) and reported a total agreement of 92.3%. Other studies have reported similar findings in terms of total IRR agreement scores,

with scores of 87.11% (Dixon et al. 2014b) and 85% (Dixon et al. 2014c).

Studies have also been conducted assessing the validity of the PEAK relational training system. Convergent validity has been assessed by correlating scores on the PEAK assessments with other similar measurement tools. For instance, Dixon et al. (2014c) correlated the PEAK-DT module with IQ. Measures were obtained for 64 participants, and the results suggested a moderately strong correlation between the two ($r = 0.759$, $p < 0.01$). McKeel et al. (2015b) correlated the PEAK-DT module with receptive and expressive one-word picture vocabulary tests (Martin and Brownell 2011a, b) and found a strong correlation between the measures. A Pearson correlation coefficient of 0.908 ($p < 0.01$) was reported for the correlation between the PEAK-DT and receptive one-word picture vocabulary tests, and a correlation coefficient of 0.901 ($p < 0.01$) was found between the PEAK-DT and the expressive one-word picture vocabulary test. In another study, researchers evaluated the relationship between the PEAK-DT, Peabody Picture Vocabulary Test (PPVT; Dunn and Dunn 2007), and Illinois Early Learning Standards. The findings revealed a strong positive correlation ($r = 0.908$, $p < 0.01$) between PEAK-DT and PPVT scores, as well as with the PEAK-DT and Illinois Early Learning Standards ($r = 0.916$, $p < 0.01$; Dixon et al. 2014b). The extent to which the PEAK-DT module was correlated with the Assessment of Basic Language and Learning Skills (ABLSS; Partington 2008) and Vineland Adaptive Behavior Scales-II (VABS-II; Sparrow et al. 2005) was conducted by Malkin et al. (2016). The authors report a strong positive correlation between the PEAK-DT and the ABLSS ($r = 0.951$, $p < 0.05$) and a moderate correlation between the PEAK-DT and the VABS-II ($r = 0.453$, $p < 0.05$). Finally, correlations between the PEAK-DT and PEAK-G modules and the Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP; Sundberg 2008) have also been conducted (Dixon et al. 2015). The analyses revealed a strong positive correlation between the PEAK-DT module and the VB-MAPP ($r = 0.93$, $p < 0.01$) and a moderate relationship

between the PEAK-G module and the VB-MAPP ($r = 0.57$, $p < 0.01$). Taken together, these data support the convergent reliability of portions of the PEAK relational training system.

In addition to convergent validity, the PEAK-DT and PEAK-G modules have evaluated in terms of their content validity (Dixon et al. 2014a, 2017). To assess content validity, PEAK-DT and PEAK-G assessments were conducted with a normative sample consisting of 206 (ages 1–21) and 183 participants (ages 1–21), respectively. Scores on the assessment were then correlated with the ages of the participants. The results suggested that assessment scores were strongly correlated with age for both the PEAK-DT ($r = 0.659$, $p < 0.01$) and PEAK-G ($r = 0.753$, $p < 0.01$) modules. The same analyses were also conducted in a sample with autism and suggest that age was not significantly correlated with assessment scores on the PEAK-DT ($n = 94$; $r = 0.021$, $p = 0.861$) or PEAK G ($n = 94$; $r = 0.200$, $p = 0.068$). Content validity has not yet been assessed for the PEAK-E or PEAK-T modules.

As previously mentioned, principal component analyses have been conducted on the PEAK-DT module (Rowsey et al. 2015) and the PEAK-G module (Rowsey et al. 2017). These analyses were conducted to assess the content validity for each of the PEAK modules. The results of the component analyses suggested that the modules were internally consistent, providing support for the content validity of the assessments. Additionally, the component analysis allowed the researchers to categorize each item within the assessment into specific factors for each module. For the PEAK-DT module, four factors were identified: (1) Foundational Learning Skills, (2) Perceptual Learning Skills, (3) Verbal Comprehension Skills, and (4) Verbal Reasoning, Memory, and Math Skills. Four components were also identified for the PEAK-G module, which include (1) Foundational Learning and Basic Social Skills; (2) Basic Verbal Comprehension, Memory, and Advanced Social Skills; (3) Advanced Verbal Comprehension, Reading and Writing, and Basic Problem Solving Skills; and (4) Verbal Reasoning, Problem Solving, Logic, and Mathematical Skills.

Taken together, these preliminary data support the PEAK relational training system as both a reliable and valid tool. The PEAK-DT module has generated the most psychometric data compared to the other three modules. The PEAK-DT module has generated test-retest and inter-rater reliability, as well as content and convergent validity. Similarly, the PEAK-G module has generated psychometric data in the form of content validity. It should be noted, however, that much of the existing psychometric data is limited to the PEAK-DT and the PEAK-G modules. The PEAK-E and PEAK-T modules have not yet generated the same amount of psychometric data. All sample sizes in the psychometric studies were relatively small, suggesting further replications are warranted.

Clinical Uses

Research supports the use of the PEAK relational training system in terms of the assessment identifying specific skill deficits an individual may have, as well as the use of the curriculum in teaching the targeted skills. Effectiveness research has emerged supporting the use of all PEAK modules (see Dixon et al. 2017). Most of the effectiveness research on the PEAK Relational Training System was evaluated utilizing single subject research designs. A number of varying skills have been targeted for program instruction, with all studies reporting positive outcomes in producing the targeted skills. A majority of effectiveness research has been conducted on the PEAK-E module; however, several studies exist for the other modules as well. Only one effectiveness study has employed a group research design in the form of a randomized control trial (McKeel et al. 2015a). In this study, the researchers compared pre-test and post-test scores on the PEAK-DT assessment for two groups of individuals with autism. One group received treatment as usual, in the form of their school's typical instruction, while the other group received PEAK-DT program instruction twice a week. The results suggested a statistically significant change in scores from pre-test to post-test for the PEAK

training group, but not for the treatment as usual group. Another study evaluated the effectiveness of the PEAK-DT module when implemented by classroom teachers and direct care staff (Dixon et al. 2018). In this study, an intervention group (19 participants) received PEAK instruction, while a quasi-randomized control group (15 participants) received treatment as usual (i.e., typical classroom instruction). PEAK-DT assessments were conducted prior to and 1 year following the intervention. The results suggested the PEAK instruction group gained more language skills than that of the control group, and the difference was statistically significant (PEAK: $M = 16.0$, $SD = 17.8$; control: $M = 6.1$, $SD = 14.4$, $F(1,33) = 10.66$, $p < 0.05$). This study supports the effectiveness of the PEAK curriculum when implemented by teachers and direct care staff, who typically have minimal training in terms of behavior analytic program instruction. Since the publication of this study, there has not been a study published utilizing a group research design for any of the other PEAK modules. Despite the lack of group design research on PEAK, significant evidence has been reported using single subject methodology which supports the use of the PEAK Relational Training System in application with autism and related disabilities.

Although the PEAK Relational Training System has generated research supporting it in terms of reliability, validity, and effectiveness, there are a few limitations worth discussing. First, only a small percentage of the overall programs have been evaluated in terms of their effectiveness. Each module contains 184 items within the curriculum. As such, research has not been conducted for every item in terms of its effectiveness in teaching the targeted skill. Second, it is recommended that program instruction for all PEAK modules be conducted synchronously; however, the extent to which the modules interact with each other has not yet been evaluated. Furthermore, normative data has not been collected on the PEAK-E or PEAK-T modules. As a result, the applicability of these modules to certain age ranges is not known. Another consideration is that reliability and validity have not yet been assessed on the PEAK-E or PEAK-T modules. Therefore,

information regarding the relative content and consistency of these modules is limited at this time. A final topic worth noting is that although the PEAK system was designed to be implemented by frontline staff and clinicians, most of the literature surrounding PEAK has been conducted by individuals familiar with PEAK programming. A few studies have incorporated the use of trainers not explicitly trained on the PEAK programming methods; however, limited research exists regarding the extent to which familiarity with programming may have on treatment outcomes.

Taken together, the PEAK Relational Training System contains an assessment and curriculum designed to identify specific skill deficits and teach the targeted skills to individuals with autism and related disabilities. Research supports the PEAK modules as a reliable and valid assessment tool, and effectiveness data support the use of the curriculum in teaching targeted skills to individuals. Overall, the data suggest the PEAK Relational Training System has demonstrated applicability to individuals with autism and related disabilities.

Pedantic Speech

Lisa Edelson
Department of Psychology, Boston University,
Boston, MA, USA
Neurocognition, Department of Brain Health,
Nestlé Institute for Health Sciences, Lausanne,
Switzerland

Definition

Pedantic speech refers to an overly formal speaking style that is inappropriate to the conversational setting. It can be characterized by didactic patterns of prosody and very precise articulation, as well as unnecessarily complex vocabulary. Some individuals diagnosed with Asperger syndrome speak in this manner, which can be an impediment to social interactions as a conversational partner may

interpret this type of speech as condescending. Pedantic speech is particularly marked in children as it is developmentally inappropriate; such children are often described as “little professors” for their very precise style of speaking.

[PEDI](#)

Description

The Pediatric Evaluation of Disability Inventory (PEDI; Haley et al. 1992) is a clinical assessment instrument designed for use with children aged 6 months to 7.5 years who have disabilities resulting in delays or impairments in functional independence. Specific applications of the PEDI include ascertaining the extent of functional delay in children, monitoring progress in rehabilitation and intervention programs, and measuring outcomes in therapeutic and educational programs. Though the instrument also may be given as part of an initial developmental or diagnostic assessment, caution is warranted because extensive validation studies of using the PEDI for this purpose have not been completed.

Administration of the PEDI is typically completed through a 45–60-min structured interview with the parent or primary caregiver, direct assessment by therapists or educators who are familiar with the child, or a combination of these two approaches. If there are severe time constraints, the PEDI may be completed directly by the parents as a “paper-and-pencil” checklist; however, the authors strongly recommend that a clinician review responses carefully with the parent and interpret the resultant data with caution.

PEDI content is based on a conceptual model that centers upon identifying the child’s functional limitations in the context of developmental expectations, task conditions, and caregiver assistance. Consistent with this model, the PEDI has three sets of scales (i.e., functional skills, caregiver assistance, and modifications), each of which is organized by three “content areas” (i.e., self-care, mobility, and social function; see Table 1). The functional skills scales include items on daily living activities, such as use of utensils, toilet transfers, and interactive play. The caregiver assistance scales assess the amount of help a child requires to complete functional skills, with responses rated on a 6-point rating system that is “weighted” so that the greatest degree of specification is provided at the “higher” end of the scale (i.e., toward the independent end). The modifications scale presents the same items as the caregiver assistance scale but asks caregivers to assess the degree to which environmental modifications and equipment are necessary for use by the child to complete functional or routine daily living

activities. The ratings from the modifications scale cannot be converted into normative data; therefore, they can only be analyzed as frequency counts.

Historical Background

The Pediatric Evaluation of Disability Inventory (PEDI; Haley et al. 1992) was developed at the New England Medical Center and first published in 1992. The development and testing of the test in the prior decade noted favorable comparison to the Battelle. The PEDI was designed to assess the functional independence of children with developmental disabilities. Scaled scores in multiple domains estimate the child’s capabilities. It has been used internationally, and in 2008, a computer-assisted version was developed (i.e., the Pediatric Evaluation of Disability Inventory-Computer Adaptive Test or PEDI-CAT).

Psychometric Data

For each of the functional skills scales and the caregiver assistance scale, two different domain scores can be determined: “normative standard scores” and “scaled scores.” The normative standard scores have a mean of 50 and a standard deviation of 10 and compare the individual child’s functioning to a group of children within the same age range in the normative sample. The normative group is composed of a small sample of

Pediatric Evaluation of Disability Inventory (PEDI), Table 1 Organization of the PEDI

Scales	Number of content items			Rating scale	Scoring system
	Self-care	Mobility	Social function		
Functional skills	63	59	65	Dichotomous	Standard scores ^a and scaled scores ^b
				Unable/capable	
Caregiver assistance	8	7	5	6-point scale	Standard scores ^a and scaled scores ^b
				“Total assistance” to “independent”	
Modifications	8	7	5	4-point scale	Frequency counts
				“None” to “extensive”	

^aMean of 50, standard deviation of 10
^bRange from 0 to 100 and used to compare child’s relative strengths and weaknesses

412 typically developing children residing in the Northeastern United States. This sample was composed of a nearly equal number of males and females (49.3% and 50.7%, respectively). Distribution by race is commensurate with 1980 US census data, with the exception of an overrepresentation of African-American children (18.7% in the normative sample versus 11.7% in the US population).

The “scaled scores” are used to provide an estimate of functional independence across the items that compose each of the scales by comparing the child’s performance relative to the maximum number of points possible (Haley et al. 1992). The scaled score range is 0–100, with “0” reflecting low functioning and “100” reflecting high functioning. These scores can be graphed on the score form for analysis of an individual child’s relative strengths and weaknesses. As the authors point out, these scaled scores do not take into account the age of the child but, rather, provide an estimate of the child’s capability in each content domain. To this end, scores can be plotted on a “score profile” located on the score summary page of the score form for visual analysis of a child’s relative strengths and weaknesses. Confidence intervals are provided for both normative standard scores and scaled scores, and a 95% confidence interval is recommended by the authors.

The PEDI manual contains evidence of high internal consistency (i.e., the degree to which the items in each of the domains measure a similar concept). Internal consistency has since been replicated and found to be adequate in a population of children with cerebral palsy (McCarthy et al. 2002). Additional evidence of instrument reliability is provided when comparing the results of separate PEDI administrations by two different examiners with two respondents who know the child well (e.g., a child’s parent and member of his or her rehabilitation team). Interrater/intrarater reliability was shown to be fairly consistent when two caregivers of a child were interviewed by the same clinician (Berg et al. 2004). However, when multiple clinicians interviewed providers, reliability of results was lower (Berg et al. 2004). Test-retest reliability data are not available.

The PEDI authors provide evidence of satisfactory validity on several dimensions. The results of reviews of the instrument by developmental experts suggest that the PEDI does measure the presence of a pediatric functional disability (i.e., content validity). A strong positive correlation between the age of the children in the normative sample and their PEDI scores suggests that the skills measured by the instrument are closely tied to overall child development (i.e., construct validity). Scores on the PEDI were found to be strongly correlated with scores on the Battelle Developmental Inventory Screening Test (BDIST; Newborg et al. 1984) for both a group of typically developing children and a group of children with disabilities (Feldman et al. 1990). Evidence of strong discriminant validity is provided in the PEDI manual as well, suggesting that the instrument effectively distinguishes between children with and without disabilities. A comparison of PEDI scores of a group of children at hospital intake for traumatic injuries with their follow-up scores at 1 and 6 months postrehabilitation showed that the PEDI detected change in the functional status of children over time, suggesting evaluative validity (i.e., the ability of the instrument to detect change in functional status of the individual).

Since its publication in 1992, the PEDI has been translated and used in several other countries with solid psychometric results (e.g., Ganotti and Cruz 2001; Wassenberg-Severijnen et al. 2003), suggesting that the instrument is a good measure of overall functional skill development. A recent attempt to abbreviate the measure and make a computer version shows promise (Coster et al. 2008). The PEDI has been utilized with a variety of populations (e.g., premature infants, brain injuries, autism, cerebral palsy) but may be best suited for populations with severe motor deficits. For example, while the PEDI has been consistently shown to be effective in identifying motor progress of children with cerebral palsy (e.g., Vos-Vromans et al. 2005), it is less sensitive in detecting subtle deficits of children with primary language impairments (Mayrand et al. 2009).

In 2012, a version of the computer-assisted version of the PEDI specifically for use with children

with ASD, the PEDI-CAT ASD, was developed (Kramer et al. 2012). Subsequent research provides some evidence that this version demonstrates strong test-retest reliability and high construct validity with children with ASD and that this instrument may be preferable over administration of lengthier instruments, such as the Vineland Adaptive Behavior Scales (Kramer et al. 2016).

Clinical Uses

For children with autism, the PEDI is most likely to be administered as part of an intake evaluation (e.g., such as during referral for early intervention services) or when there is a concern about additional physical disabilities or delays that impact the independent functioning of the child. Given the “prompt dependency” that many children with ASD demonstrate (i.e., the necessity of caregivers to direct a child to initiate and/or complete a task that is otherwise within his or her skill repertoire), the PEDI may be a useful tool for monitoring independence and timely use of functional skills. Repeated administrations of the PEDI as part of ongoing treatment for a child with ASD may allow caregivers and clinicians the ability to monitor progress with functional skills over time. Given that the data used to establish the norms were collected over 30 years ago, it is recommended that normative standard scores be interpreted with great caution.

The PEDI is most useful in the assessment of children with motor disabilities such as children who were premature infants or who have cerebral palsy.

Pediatric Speech Intelligibility Test

Jennifer McCullagh

Department of Communication Disorders,
Southern Connecticut State University, New
Haven, CT, USA

Synonyms

PSI test

Description

The Pediatric Speech Intelligibility (PSI) test is a closed-set test composed of 20 monosyllabic words and a 10-sentence procedure. The monosyllabic word lists consist of simple nouns like “bear” and “fork.” The sentences consist of two formats. In the first format, the sentences are composed of a noun phrase, verb-ing, and a noun phrase and are preceded by the carrier phrase “show me.” An example of a sentence in the first format is “Show me a rabbit painting an egg.” In the second format, the sentences are composed of a noun phrase, auxiliary verb-ing, and a noun phrase. An example of a sentence in the second format is “A rabbit is painting an egg” (Jerger et al. 1980; Northern and Downs 2002). The child is instructed to point to one of the five pictures corresponding to the sentence or word that is heard (Jerger et al. 1981). The PSI test can be administered in quiet, as well as in the presence of a competing message.

Historical Background

The Pediatric Speech Intelligibility (PSI) test was developed to evaluate both peripheral and central components of auditory disorders in children between the ages of 3 and 6 years. The test takes into consideration children’s receptive language function since the test stimuli were generated by typically developing children between 3 and 7 years of age. The word and sentence stimuli

were elicited by picture stimulus cards which were chosen from lists of words and actions comprising the vocabularies of young children (Jerger et al. 1980).

Psychometric Data

Validity studies using the PSI test indicate that test performance on the Format I and Format II sentences was significantly different in children between the ages of 3 and 6 depending on their chronological age as well as receptive language ability. Performance on the monosyllabic word materials did not change with receptive language abilities. Trends in chronological age were evident for both the word and sentence materials (Jerger et al. 1981). Performance intensity functions were reported in quiet and in noise and performance reached 100% in children with normal hearing on words and sentences in both quiet and noise at a presentation level of 50 dB SPL (Jerger and Jerger 1982). Test-retest measures indicated high test-retest reliability for both normal hearing and hearing-impaired children (Jerger et al. 1983). Furthermore, the PSI test has been shown to have high sensitivity and specificity to central auditory nervous system lesions in children (Jerger 1987).

Clinical Uses

The PSI test has been used to evaluate speech intelligibility in quiet and in noise in a variety of populations, both children and adult as follows: speech intelligibility in children with recurrent otitis media (Jerger et al. 1983), central nervous system lesions (Jerger et al. 1983; Jerger 1987), and hearing impairment (Jerger et al. 1983). In addition, the PSI test has been used to evaluate speech intelligibility in children with cochlear implants and hearing aids (Somers 1991). Clinically, the person administering the PSI should take into consideration the cognitive, hearing, speech, and language abilities of the individual being tested as these factors may affect outcomes. Thus, the PSI is not typically administered to children with autism, and performance on this test should be interpreted with caution in this population.

Peer Mentors for Students with ASD on College Campuses

Barbara A. Cook¹ and Deborah Weiss²

¹Department of Communication Disorders, Center of Excellence on Autism Spectrum Disorders, Southern Connecticut State University, New Haven, CT, USA

²Department of Communication Disorders, Southern Connecticut State University, New Haven, CT, USA

Definition

A peer mentor is an individual with an expected level of experience in a particular area who

provides support to a similar-aged individual with less experience in that area (mentee). The critical roles of peer mentors on college and university campuses include support in coursework, degree completion, and navigation of social networks.

In this model, peer mentors typically share common characteristics, attributes, or circumstance with the mentee in such areas as age, ability, interests, or community environment (i.e., school, classes, dormitories, etc.). The desirable traits and skills of peer mentors include patience, flexibility, and effective communication. Peer mentors typically receive training that provides them with skills such as effectively using peer modeling to demonstrate appropriate utilization of targeted skills, facilitating interaction, and providing indirect guidance and positive reinforcement (Battaglia and Radley 2014). The peer mentor/mentee relationship should be one of reciprocity (Gilman 2006); therefore, at its very core, this model provides support on a social level.

Historical Background

Over the last 10–15 years, there has been an increase in the number of adults with autism spectrum disorder (ASD) who are capable of engaging in postsecondary education. The literature indicates, however, that many of these individuals either do not attend an institution of postsecondary education or, when they attend, struggle with successful completion of a terminal degree (Shattuck et al. 2012). Overarching factors that negatively impact success include challenges in the areas of social interaction, executive function, and emotional regulation (Adreon and Durocher 2007; Gotham et al. 2015). Many who do complete a terminal degree experience difficulty securing gainful employment; this appears to be connected to ongoing challenges with social interaction and poorly developed social capital (Dipeolu et al. 2015).

Social capital refers to connectedness and engagement with individuals, organizations, and communities. Higher levels of social capital are linked to better outcomes in education,

employment, health, political participation, safety, and well-being for all individuals (Clark et al. 2015; Hill 2011; Seibert et al. 2001). Building social capital takes time and investment and a strong capacity for socially interacting with a variety of individuals. Students with ASD who attend postsecondary education institutions have difficulty building social capital due to numerous challenges they face in areas such as time management, social interaction, emotional regulation, and navigation of the curriculum.

Many students with ASD, who received support or accommodations in secondary education, no longer receive assistance at their postsecondary education institutions for a variety of reasons, including a lack of willingness to disclose their disability. Furthermore, there is a lack of knowledge and understanding of autism by peers, student affairs staff, and faculty which further impedes potential natural support across multiple settings (Van Hees et al. 2015). Gelbar et al. (2014) reviewed 20 articles that focused on the collegiate experiences and/or support of students with ASD. Commonly reported emotions among these students included anxiety, loneliness, depression, and peer rejection; all factors possibly related to poorly developed peer networks and lower levels of social capital. The authors concluded that there is a scarcity of research on postsecondary education experiences of students with ASD, noting that most articles are case studies and very few are empirical in nature.

It is crucial to identify the most effective supports to address core challenges so that these capable individuals will be able to live up to their potential to complete a postsecondary education degree. One such support, commonly referred to as peer-mediated intervention or peer mentoring, is rising in popularity. Given the current ubiquity and success of peer mentor programs on college and university campuses, it would appear to be a reasonable approach with significant potential. Peer mentors can assist students with ASD by modeling social behavior, assisting in making new friends, and supporting involvement in extracurricular activities, areas critical for the development of a peer network and increased levels of social capital.

Current Knowledge

Evidence exists to support the value of the use of peer mentors in the college setting for all students, particularly for incoming freshmen. These types of interactions provide the opportunity for students to build social networks. Social networks that are developed with faculty, staff, peers, friends, and mentors are strongly linked to student success, e.g., satisfaction, persistence, etc. (Kuh et al. 2012). In addition to acknowledging the effectiveness of peer mentors for all students at the college level, evidence of how to use peer mentors to increase social and academic success for individuals with ASD is needed if this is to be considered a reliable support. There is ample evidence in the K-12 setting of the effectiveness of the use of peer mentors to assist students with ASD in improving social interaction, emotional regulation skills, and academic skills (Hart et al. 2010; Tichenor 2016).

The strategies used in studies of peer-mediated intervention (PMI) in the secondary education population may be useful for students in postsecondary education. Bambara et al. (2016) trained a group of high school students for a period of 18 weeks, 3–4 days per week, to serve as conversational peers to three students with ASD. At the end of the intervention period, the authors found an increase in the following: number of conversational acts, initiation and length of conversations, asking of follow-up questions, making comments, and assertive conversation acts. The authors cited the necessity of systematic intervention in training the peer mentors, concluding that proximity alone would not be sufficient to promote the social interaction. Although there is a paucity of research that addresses the utilization of peer mentors in assisting students with ASD in institutions of postsecondary education, it is reasonable to assume that many of the same factors that have led to success with younger students would also apply to this age group.

Peer mentors have been observed to be helpful in modeling appropriate social behavior and assisting students with ASD in meeting new friends and broadening their friendship circle at the precollege level. However, given the shift in

the structure and ambiguity of social engagement that occurs at the college or university level, it is necessary to investigate the feasibility of implementing a structured, formal peer mentor program at this level. Neville and White (2011) surveyed college students with typical development (TD) regarding their openness to peers who demonstrate behaviors typical of individuals with ASD. Results indicated that students who have a first-degree relative with ASD are more open to college peers with ASD and are more likely to be comfortable socializing and/or living in close proximity to them, suggesting a link between awareness and comfort levels. A follow-up study conducted by Gardiner and Iarocci (2014) revealed similar findings. In addition, they found that student acceptance of individuals with disabilities increased the possibility of intent to volunteer. Therefore, if a college or university systematically increases awareness of autism, there will potentially exist a strong pool of peer mentors to assist with the development of social networks, thus leading to increased social capital and the fostering of success in the ASD college population.

Several studies have explored the use of systematically trained and engaged peer mentors at the college or university level geared toward students with ASD. A 1-year longitudinal study (Madriaga et al. 2008) was completed in the United Kingdom that examined the postsecondary education experiences of 1st-year students with ASD. Eight students, across six different universities, were followed for a period of 1 year. Among the goals of the study were to enable a wider group of students with ASD to achieve postgraduate education, raise the profile of students with ASD, promote issues of awareness and disability among staff, and understand societal barriers in order to facilitate a more successful transition to the postsecondary education setting. Six of the eight students were assigned mentors at some point during the year. The narrative reports of the experience with the peer mentors were largely positive. The mentors were viewed as mediators, counselors, or simply as individuals who were available to help. This further supports the feasibility and positive impact of the use of peer mentors.

Weiss and Rohland (2015) reported success in the use of a form of peer mentor support at the University of Rhode Island (URI) in their Communication Coaching Program. Group communication coaching sessions for students with ASD focused on teaching skills to support social communication and executive function. Peer coaches, paired with these students, reinforced the skills in natural settings across the campus. Over the course of 5 years, 55 students (which represented 42% of the students who self-identified with ASD) chose to participate in the program. Progress reports written by the coaches revealed growth in social communication skills, particularly for conversational management; all participants were successful in completing their degrees at URI. The authors of this program acknowledged a need for additional systematic data to further support the effectiveness of peer coaches on the success of this population of students.

Ames et al. (2015) reported on a relatively long-standing mentorship program at York University in Toronto. Overarching goals of the program were for students to feel a sense of belonging within the university community and to assist the students in building a peer network while building social, organizational, and vocational skills. Students were paired with graduate student mentors from the clinical psychology program who had extensive clinical experience and academic knowledge of ASD. Mentors and mentees met weekly, and there were additional group meetings and events that took place regularly. Evaluation of the success of the program was based on a number of measures, including personal interviews, year-end evaluations, student participation, student satisfaction, etc. More than half of the mentees reported meeting weekly with their mentors and high levels of satisfaction in achieving their goals.

Siew et al. (2017) described a mentoring program at Curtin University in Perth Western Australia in which ten undergraduate students with ASD were individually mentored by an undergraduate or graduate student for up to 2 h weekly for one semester. The mentors and mentees also attended weekly group sessions that addressed a number of different topics. The mentors participated in a training program and

met weekly for group supervision sessions. Questionnaires were completed by the mentees pre- and post-study. Results indicated a perceived increase in social support and a reduction in general communication apprehension. Overall anxiety scores, however, did not demonstrate a pre-post change. Qualitative results indicated three positive features of the program: constant and stable support, comfort of peer-to-peer support, and flexible and individualized support. Mentors reported a high level of participant satisfaction, demonstrated a 29% pre-post increase in acquisition of knowledge regarding autism, and reported an increased awareness of some challenges faced by individuals with autism, including sensory differences, anxiety, and underlying cognitive processes (Hamilton et al. 2016).

In a unique approach, Cook and Weiss (2016, 2017) reported on a 3-year pilot study in which the building of social networks was accomplished through an undergraduate college class. The course, comprised of students with ASD or other social communication challenges and undergraduate students with typical development, provided students with an in-depth study of social communication and cognition and provided a context to support students with personal or professional challenges. Graduate students of speech-language pathology participated in the study as student teachers. The classroom environment was designed to facilitate the incidental development of peer support networks. Daily group activities and regular rotation of students in the class among the groups ensured that there would be ample opportunity for students to interact with all members of the class. Typical activities included role-play scenarios, review and analysis of targeted movie scenes, and the creation of group and/or individual videos for analysis. In addition, readings on peer mentoring were assigned and were incorporated into focused discussions with the intent of facilitating mentoring opportunities within and external to the class for the students.

Student course reviews indicated a very high level of satisfaction with the class. Pre-post surveys demonstrated an increase in some measures of overall level of comfort toward individuals with ASD among the students in the class with

typical development. In pre-post questionnaires, the student teachers demonstrated a statistically significant increase in multiple aspects of understanding and feeling comfortable facilitating peer mentorship activities, while course participants demonstrated a statistically significant increase in a basic level of understanding peer mentorship. Observations of the class during a pre- and post-class social activity indicated increased social interaction and initiation among all students. The advantage of such an indirect approach to peer mentorship is the potentially more naturalistic development of peer networks when compared to a more systematic, direct instructional approach such as the one described by Bambara et al. (2016). In one instance, a peer mentor-mentee relationship developed between two of the course participants. Both individuals reported that the opportunities provided in the class contributed to the development of their relationship. In addition, the indirect approach reduces the necessity for the student with autism to self-disclose.

Future Directions

As the number of students with ASD continues to grow at the college and university levels, it will be necessary to provide appropriate supports and services that enable these students to successfully complete their programs of study. Although student resource support offices typically provide academically based supports, they often do not provide adequate support in the areas of social interaction and communication. In addition to experiencing academic challenges related to executive function, individuals with ASD face greater challenges in social interaction skills and require support in these areas in order to be afforded an equitable opportunity for success in their programs of study.

Given the past and current successful use of peer mentors for all students at the college or university level, it is imperative that these institutions continue to explore and expand upon this support. Fortunately, there currently exist a growing number of programs that provide peer mentors for students with ASD that can be tapped to learn

about the best approaches for a particular college or university. In addition, there is clear evidence that supports ease of implementation of such programs when they are combined with either existing peer mentor programs or a college level course. It is possible to provide training to existing peer mentor volunteers in the area of ASD while working toward developing a more systematic program. This approach is supported by the research of Nevill and White (2011), Gardiner and Iarocci (2014), and Cook and Weiss (2016, 2017a, b) that has demonstrated that increasing knowledge and awareness of ASD and facilitating contact with individuals with ASD increases the willingness to support these individuals.

A review of the literature reveals a paucity of empirical studies that have investigated the effectiveness of peer mentors on postsecondary outcomes for college-aged students with ASD. Most of the literature consists of qualitative analyses and includes narrative accounts of approaches used to implement peer mentor programs. Although these latter articles are promising, additional empirical research is needed to determine whether or not peer mentoring can be adopted as an evidence-based practice for this population. In order to increase the quantity of empirical research, collaborations between practitioners and researchers should be encouraged. Together they can identify the most appropriate empirical research design to study the effects of systematically developed (direct) and/or naturally occurring (indirect) peer mentor-mentee relationships. Critical outcomes to be measured are the impact on degree completion, gainful employment, and positive community engagement.

Definition

Peer victimization is typically defined as being the target, directly or indirectly, of an aggressive action. In this context, aggression is defined as an action/behavior that is intended to harm the target of that action/behavior. Here, it is important to distinguish between the terms peer victimization and bullying, which are often incorrectly used to mean the same thing. Bullying refers to being a target of aggression, but differs from peer victimization in that bullying requires that the aggressor has power – in terms of status, physical size or strength, or psychological control – over the target of the aggression. Thus, all bullying falls under the definition of peer victimization but not all peer victimization falls under the definition of bullying. Peer victimization targeting those with ASD, in most instances, should be classified as bullying since the symptoms of ASD and associated social difficulties make it unlikely that they have more power than someone targeting them. Similarly, in many cases, the aggressive actions by those with ASD would not be classified as bullying since those with ASD often do not have power over the targets of their actions. Instead, much of the aggression that individuals with ASD exhibit is considered reactive aggression rather than instrumental aggression to be used as a tool for maintaining power over the individual being targeted.

Using terms like bullying, teasing, or being mean in the measurement of peer victimization

Peer Supports

► Interpersonal Supports

can be problematic since these terms, from the perspective of participants, can be subjective, interpreted quite broadly, and are often seen as being synonymous with one another. In measuring peer victimization, it is critical to use items that describe the specific aggressive behaviors (e.g., hit, kick, call me mean names) targeted at the victim. This specificity impacts measurement validity and in turn internal validity of studies of peer victimization. It is also important to distinguish between the various forms of peer victimization, such as physical, verbal, electronic, relational, and physical. This is key to building effective intervention strategies since different forms of peer victimization are associated with different outcomes and predictors (see next section).

Historical Background

Not relevant

Current Knowledge

This section will outline the current knowledge about the prevalence of peer victimization in children and adolescents with ASD, as well as the factors found to be associated with peer victimization in this population.

Prevalence of Peer Victimization

Rates. Numerous studies indicate that individuals with ASD tend to be viewed less positively by their typically developing (TD) peers (Bauminger and Kasari 2000; Chamberlain et al. 2007; Humphrey and Symes 2010, 2011; Jones and Frederickson 2010; Locke et al. 2010; Lyons et al. 2011; Petrina et al. 2014; Wright and Wachs 2019). Thus, it is not surprising that children and adolescents with ASD are commonly targeted for peer victimization. Multiple studies have shown that those with ASD experience higher rates of peer victimization than TD peers (Bear et al. 2015; Chan et al. 2018; Humphrey and Symes 2011; Rose et al. 2015; Rowley et al. 2012; Twyman et al. 2010; Wainscot et al. 2008; Zeedyk

et al. 2014) and peers with other disabilities (Humphrey and Symes 2011; Rowley et al. 2012; Twyman et al. 2010; Zeedyk et al. 2014). Parents of children and adolescents with ASD report peer victimization rates ranging from around 40% to 90% across studies (Cappadocia et al. 2012; Little 2002; Maiano et al. 2016; Pfeffer 2016; Sterzing et al. 2012), with variability across studies explained, to some extent, by the time frame used for measuring peer victimization (Maiano et al. 2016; e.g., lifetime vs. weekly occurrence). Nevertheless, even if the true rates of peer victimization for this group fall at the lower end of this range that would indicate a substantial number of individuals with ASD are encountering negative peer experiences.

Types of victimization. A few studies have examined differences in rates for different types of victimization, such as verbal, relational, and physical (Adams et al. 2014; Bear et al. 2015; Kloosterman et al. 2013; Maiano et al. 2016; Nowell et al. 2014; Wainscot et al. 2008; Zeedyk et al. 2014). Overall, these studies find that verbal victimization occurs the most often, which is similar to what is seen in studies of TD children and adolescents. Findings have been mixed when examining frequencies of relational and physical victimization relative to TD peers (Adams et al. 2014; Bear et al. 2015; Kloosterman et al. 2013; Zeedyk et al. 2014). More recently, studies have also examined cybervictimization in those with ASD, finding similarly high rates as those found in more traditional types of peer victimization. Further, cybervictimization was associated with depression and anxiety (Ashburner et al. 2019; Kowalski and Fedina 2011; Wright and Wachs 2019).

Factors Associated with Peer Victimization

To obtain a more complete picture of peer victimization in children and adolescents with ASD, some studies have begun to test the associations between peer victimization and various correlates. Here studies are reviewed that identify which individuals with ASD are at-risk for being targeted and outcomes associated with victimization.

Which individuals with ASD are targeted. One of the more consistent findings related to risk for

victimization is that those in general education setting are more likely to be targets of peer victimization than those in special educational settings (Bitsika and Sharpley 2014; Blake et al. 2012; Maiano et al. 2016; Zablotsky et al. 2013; Zeedyk et al. 2014). Thus, studies focused on negative peer experiences may want to put a special focus on individuals who are “mainstreamed” in general education.

A few studies have tried to understand how variability in social-communication skills in this group might be associated with peer victimization, with mixed findings (Cappadocia et al. 2012; Chou et al. 2019; Fink et al. 2018; Rowley et al. 2012; Sterzing et al. 2012; Storch et al. 2012). Some of these studies find social-communication skills to be positively associated, others negatively associated, and some studies find null effects. A few explanations have been provided for these discrepant findings: higher abilities may make it more likely that self-reporting adolescents with ASD are aware of these negative interactions, or it may be that certain settings (e.g., mainstreamed classrooms or unsupervised settings) can result in difficulties in social-communication skills becoming more or less of a liability for being a target of peer victimization. In other words, if individuals with better skills are more likely to have access to more inclusive environments, this may raise their risk of being targeted by similar-aged peers.

Outcomes associated with victimization. Externalizing problems, such as poor impulse/emotional control, ADHD, and aggression, are commonly found to both predict and result from peer victimization experiences in TD children and adolescents (Card and Little 2006). Similarly, externalizing problems (which commonly co-occur with ASD) are associated with peer victimization in individuals with ASD (Cappadocia et al. 2012; Chou et al. 2019; Hebron and Humphrey 2014; Rieffe et al. 2012). Recent studies suggest that special attention should be given to situations when classmates provoke an aggressive reaction from their ASD classmate by purposely directing behaviors that they know will make their ASD classmate overreact emotionally (i.e., “meltdown”; Zablotsky et al. 2013).

Among adolescents with ASD, peer victimization has also been found to be associated with internalizing problems such as symptoms of depression and anxiety (Adams et al. 2014; Cappadocia et al. 2012; Rosbrook and Whittingham 2010; Storch et al. 2012; Ung et al. 2016; Wright and Wachs 2019). This association is particularly significant given that lifetime estimates of internalizing disorders for those with ASD are as high as 52% for depression and 65% for anxiety disorders, compared to rates of 5% and 20% reported in TD adolescents (Costello et al. 2005a, b; Lever and Geurts 2016; Leyfer et al. 2006; van Steensel et al. 2011). These higher rates of internalizing problems might result, at least in part, from peer victimization experiences.

Finally, peer victimization has been shown to be associated with school outcomes in individuals with ASD. Adams et al. (2016) found, in two separate data sets, that both parent- and peer-reports of peer victimization were associated with feelings about school (i.e., safety, liking, belonging), behavioral problems at school, and academic performance problems. Similar to internalizing symptoms, associations between peer victimization and school experiences are particularly concerning given the overwhelming problems that adolescents with ASD have with these same school outcomes. Even among those with high cognitive abilities, relative to TD peers, individuals with ASD underperform across various measures of academic performance (Ashburner et al. 2010; Estes et al. 2011; Jones et al. 2009; Keen et al. 2015; Wei et al. 2013) are less likely to enjoy school, less likely to engage cooperatively and independently at school (Jahromi et al. 2013), and more likely to be removed from a public educational setting by way of either suspensions (Starr and Foy 2010) or being home schooled (Parsons and Lewis 2010). Similar to internalizing, these high rates of school problems might be a caused, in part by peer victimization experiences.

Future Directions

The first substantial wave of studies examining peer victimization in children and adolescents

with ASD has occurred over the past 7–10 years, and now the next wave of studies that build upon the finding of these early studies is beginning. The following are three suggested areas that should be considered for the next wave of studies.

Advanced methods. Most of the initial studies on peer victimization in ASD were cross-sectional survey studies that utilized single-item measures to test questions of the frequency of the occurrence of peer victimization. Studies utilizing more advanced methods have just started to appear, and this trend must continue in order to inform the development of interventions that target these negative peer experiences. The focus must move from testing frequencies of these experiences, to testing associations between predictors and outcomes so that specific processes of peer victimization can be identified for this group. While it is known that those with ASD are common targets of peer victimization, little is known about what this process looks like, who is targeted, why they are targeted, or the long-term ramifications of these experiences. Unfortunately, studies that test such associations are all cross-sectional. This means that we do not yet know if a construct under study is a predictor of and/or an outcome of peer victimization. This is particularly problematic because many constructs that have been shown to be important for understanding peer victimization are both predictors *and* outcomes in studies of TD populations. For instance, among TD children, internalizing problems are both predictors and outcomes of peer victimization (Reijntjes et al. 2010).

Additionally, the dearth of longitudinal studies has resulted in a lack of understanding of the developmental trajectories of peer victimization over the course of childhood and adolescence (e.g., when do rates peak? decrease?). Finally, the field must move away from using single item measures (e.g., is your child bullied) and ensure that the measures being utilized provide proper measurement validity. Not only should these measures have multiple items that tap into various forms of peer victimization that this group experiences, but these measures should be tested to ensure that they are psychometrically sound, especially for self-reports. Self-report measures of

peer victimization are very important for understanding such experiences and their outcomes (e.g., Adams et al. 2014). Particularly for those who spend a majority of their school in inclusive settings, there might not be adults present to witness such experiences and thus self-reports are crucial.

Predictors. For many groups at heightened risk for being targeted for peer victimization, it is a unique physical characteristic that makes them a target, such as being obese (Adams and Bukowski 2008; Adams and Cantin 2013). Those with ASD often do not, at first glance, appear physically different than their peers. Instead, it is the behaviors they exhibit that may cause them to seem different and, in turn, put them at risk for being targeted for peer victimization. However, there is tremendous phenotypic heterogeneity in the behaviors exhibited by adolescents with ASD; knowing what puts someone with ASD at increased risk for negative peer experiences requires more than simply knowing that he/she has ASD. For example, it is possible that any number of common ASD symptoms, including decreased social and emotional insight, restricted and repetitive behaviors, or communication difficulties, as well as common behaviors exhibited by this group (e.g., issues of hygiene, tattling, rigidity around rule breaking), might potentially place this group at increased risk for negative peer experiences. Future studies must test the various symptoms of ASD, as well as the various comorbid problems and behaviors, as possible predictors. Until these predictors are known it is difficult to create interventions to address this issue.

Gender. Gender differences are apparent in studies of TD adolescents across most aspects of social development (Rose and Rudolph 2006), as well as in peer victimization (e.g., rates of different types and content of victimization; Hong and Espelage 2012). Males and females often experience different forms of bullying, with boys experiencing more physical bullying (Carbone-Lopez et al. 2010), girls experiencing more relational forms (Murray-Close et al. 2007), and boys and girls experiencing similar levels of verbal bullying but with topics of verbal bullying differing by gender (Duncan 1999; Gruber and Fineran

2008). Because social experiences often vary as a function of gender, successful interventions targeting social experience *must* take gender into account. A few studies have examined gender differences in global peer victimization for those with ASD and found no gender differences. This is not surprising, as many studies in TD individuals also find no gender differences when examining only global indicators (as already stated, differences emerge when examining types of peer victimization) (Fink et al. 2018; Schrooten et al. 2018; Ung et al. 2016). There has been one study that tested gender differences for various types of peer victimization among those with ASD and found a marginal effect (e.g., $p = 0.10$) for relational aggression (Ung et al. 2016). It is important to note that most studies are underpowered to detect gender differences, as ASD samples tend to be small and occur in four to five males for every female (CDC morbidity and mortality report, 2018). Future research with larger samples is needed to understand peer victimization experiences of males vs females.

Peer-Mediated Intervention

Kathy Thiemann-Bourque
 Schiefelbusch Institute for Life Span Studies
 Juniper Gardens Children's Project, University of
 Kansas, Lawrence, KS, USA

Definition

Peer-mediated interventions (PMIs) involve training peers without disabilities to be responsive and

interactive social partners to children with autism spectrum disorders (ASD). Both peers and students with ASD are taught to initiate and respond to each other within engineered (i.e., instruction in small groups) and typical school social contexts (e.g., centers, game play, recess, and lunch) across the school day. For adolescents with ASD, programs involving peers without disabilities are generally referred to as peer networks. A group of 5–6 peers is recruited and meets regularly to plan social activities, seek solutions to social problems, and create daily opportunities for students with ASD to have positive social experiences both in and outside of the classroom. The primary focus of PMIs, regardless of age, is to increase social reciprocity, positive interactions, and possibly the development of friendships.

Historical Background

The concept of training peers without disabilities to be responsive social partners to young children with autism began in the 1970s. This landmark research was particularly important given the core deficits in social communication characteristic of autism and failure to develop peer relationships (American Speech-Language-Hearing Association [ASHA] 2006). In the 1980s, these initial positive findings were replicated, and different PMI approaches were explored with preschoolers with much success. Some of these approaches included teaching peers to (1) use responsive language facilitation strategies (e.g., repeat and expand on language used by focus child with autism), (2) use social initiation strategies (e.g., establish joint attention, initiate play routines, comment on one's own play), and (3) learn language scripts that matched dramatic play themes (e.g., hamburger stand, birthday party) (Goldstein et al. 2007). In the 1990s, PMI approaches were extended to include elementary school-age students with ASD and, to a lesser degree, middle school and high school students. The focus over the last decade has been to create comprehensive school-based PMIs that integrate peer training with evidence-based direct instruction to achieve more widespread and robust social outcomes in inclusive settings.

Two instructional approaches more recently incorporated within PMIs are video modeling and the use of written-text or graphic-cueing systems (Thiemann and Goldstein 2001; Thiemann-Bourque and Goldstein 2004). For example, social group interactions can be videotaped then played back for self-evaluation and feedback. Words or short phrases (written-text cues) are used to prompt what to say in a specific social context, along with picture symbols or photographs of children interacting. These strategies capitalize on visual learning styles and strengths of children with autism.

Rationale or Underlying Theory

Friendships build on social interactions. There must be opportunities for interactions and the outcomes of those interactions must be positive for friendships to begin to develop. Social interdependence theory considers how the rewards or benefits of a social interaction outweigh the costs. It is more likely that children will engage in social interactions when their social exchanges are rewarding and fun than if interactions require effort to maintain. This applies to both children with autism and those without developmental disabilities. Adults in the children's environment are the key to planning effective social programming to assure maximum benefits for all involved.

In inclusive settings, exposure to peers alone is not enough to impact the social and communication deficits characteristic of children with ASD. When an adult sets up the social environment to meet individual child needs, then models, prompts, and reinforces social communication and social responsiveness – many benefits can occur. For students with ASD, involvement in PMIs usually leads to increased reciprocal communication with peers, greater friendship ratings among classmates, and a decrease in behaviors that can lead to awkward or uncomfortable interactions. Group contexts provide naturally occurring social opportunities with socially sophisticated peers who can model important communication skills. Consequently, children with ASD will have a greater chance of generalizing communication

skills across social settings and partners. Benefits to peers include learning social and communication skills to engage in positive interactions with children with disabilities and other classmates and enjoyment in helping others. Further, involving available peers as social change agents can decrease time demands on teachers or other staff and lead to spillover effects to untrained peers. Without training, peers may reinforce children's inappropriate social behaviors and ignore desirable behaviors.

Several possible reasons may explain the benefits of using written-text, graphic, or other picture cues to teach social communication within peer groups. First, it is a widely held belief that children with ASD have a superior ability to recall visually presented information (Grandin 1995). Second, written-text cues are basically “scripts” that provide children with constant access to a relevant and appropriate “social outline” to follow and language to use within a social context. Peers are taught to remind focus children to use this cue to initiate, respond, and stay engaged in the interaction. Third, having picture and text cues available throughout an activity provides opportunities for repeated practice of the same target skill(s), and when peers express the same utterances, they provide many models of the skill in a short time period. For children who are verbal yet not intelligible, communication attempts will be better understood given that everyone in the group knows the target communication skill and script. Finally, peers provide feedback on the timing and social appropriateness of the child's behavior in different social contexts. This feedback and reinforcement may lead to greater independent use of targeted communication skills.

Goals and Objectives

The primary goals and objectives of PMIs are:

1. To include peers as intervention agents and train them to use strategies that lead to successful social exchanges with children with ASD
2. To provide regular and frequent opportunities for children with ASD and peers without disabilities

to practice age-appropriate social communication skills in typical school social settings

3. To provide direct instruction that increases children’s repertoire of verbal and nonverbal social communication behaviors to (for example):
 - Engage in joint play routines
 - Respond to peer’s bids for joint play
 - Take turns and share
 - Gain attention/greet others
 - Comment or describe actions and objects
 - Request actions, objects, or information
 - Keep talking to maintain topics
 - Be flexible about topics
 - Use social niceties (e.g., compliments, cheers, and sharing affection)
4. To improve reciprocal child-peer social interactions and enjoyment across varied social activities and environments
5. To reduce the divergent social path and social competency gap that occurs between children with and without ASD as they advance through higher grades
6. To foster friendships and relationships between individuals with and without ASD

Children with better social skills are more likely to make friends, and having friends further supports the acquisition of social skills. If appropriate social skills provide a foundation for relationship and friendship development, what social goals are most important? Table 1 lists possible social communication targets that can lead to improved initiations and reciprocal interactions for young children with ASD. The difficulty in deciding which skills to teach is complicated by two factors. Children need to learn not simply a repertoire of skills but when to use which social skills, when to vary them based on the situation, with what frequency of use, and such. This is further complicated by the need to adjust to the ever-changing expectations of one’s peer group, family members, teachers, and community members as the child grows older. Thus, the interventionist needs to be cognizant of shifting social demands and plan ahead to equip children with social skills that will be needed in future social encounters.

Peer-Mediated Intervention, Table 1 Potential social communication goals and example written-text cues

Preschool	School age
Descriptive comments (e.g., “I have two”; “Mine is blue”)	Descriptive comments (e.g., “You have a match”; “I got one!”)
Provide assistance/offer help (e.g., “You want help?”)	Requests for actions or objects (e.g., “Roll it” or “Can I have the dice?”)
Share/give/accept toys (e.g., “Here you go” + giving toy)	Requests to gain information (e.g., “What do I do?”)
Establish joint attention (e.g., tap on shoulder, move closer)	Secures for attention (before initiations) (e.g., “(name), _____” or tap on shoulder)
Provide affection and praise (e.g., high five, pat on back)	Social niceties (e.g., “Way to go!” or “Maybe next time”)
Play organizers (e.g., “Let’s play _____”; “You be the cook”)	Make suggestions (e.g., “I have an idea, let’s do rock-paper-scissors”)

Treatment Participants

PMI approaches have been successfully implemented for individuals with autism spectrum disorders (ASD), including autism, Pervasive Developmental Disorder-Not Otherwise Specified (PDD-NOS), and Asperger’s syndrome. Participants with ASD are most often between the ages of 3 and 13 years and attend preschool or elementary school with typically developing peers. However, with modifications, peer network programs can be successfully implemented for middle and high school students as well (Thiemann-Bourque 2010). Participants with ASD demonstrate a wide range of cognitive, social, and communication impairments. Peer implementers are generally the same age as their classmate with ASD and are recruited based on select criteria (see section “[Peer Participation](#)” below):

1. Age-appropriate social skills
2. Has similar interests to student with ASD
3. Well-liked by the majority of classmates (i.e., high-status peers)
4. Consistent school attendance
5. Similar academic groupings or classes with student with ASD

6. Not overtly shy or quiet
7. Willingness to participate

Treatment Procedures

Selecting Instructional Strategies

Successful implementation of PMIs can be accomplished by attending to the intervention components listed in Table 2. These are established guidelines for planning, implementing, and monitoring PMIs, with the understanding that there is an ongoing need to examine specific social behaviors to teach and in what contexts to optimize the social outcomes. The following guiding principles can be used to select instructional strategies (Goldstein and Kaczmarek 1992):

1. Strategies that teach behaviors observed in high-quality interactions between children in general (e.g., engagement, responsiveness, and smiling or other expressions of positive affect)
2. Strategies that have a higher chance of eliciting responsive social behaviors (e.g., mutual attention to an activity, descriptive comments about current activity, and acknowledging a speaker’s communication)
3. Strategies that generate reciprocal interactions as reflected in more balanced turn-taking (e.g., sharing objects in play, taking turns in games, and being verbal in conversations)
4. Strategies that optimize the social environment to enhance social interactions between children with and without ASD (e.g., attention to group size, use of preferred activities and activity choices, and adult guidance)

Peer-Mediated Intervention, Table 2 Components of comprehensive peer-mediated school social programs

Component	Description and examples
Supportive social environment	Visual schedule of group events, choice of two preferred and motivating activities, outline expectations and social roles, games with simple rules, 1–2 peers involved at one time
Regular social opportunities	Structured: 3–4 times/week for minimum of 15–20 min Less structured: 5–10 min across daily school routines
Naturalistic settings	Free play, centers, thematic play (e.g., grocery store, restaurants, hairdresser), phonics or math games, snack, recess, lunch, social activities before or after school
Age-appropriate activities	Board games, art projects, science experiments; incorporate interests and familiar themes so motivating and fun for all
Visuals and picture cues	Peer “buddy” manual of targeted social skills; conversation topic starter cards; real photographs of the children; placemats at snack or lunch with topic starters Velcroed on silly pictures, favorite foods, cartoon characters, etc.
Written-text cues	Write out 2–3-word simple phrases on skill sheets or in topic bubbles that match the game/ social context; represent social skills with pictures or line drawings; peers use same cues as focus children; place in 5 × 7 or 8 × 10 clear photo frames
Peer training	Recruit 4–6 peers; well-liked and same age; teach 3–5 facilitative or responsive social skills; peers cue focus child to talk/interact using written-text and picture cues; peers can be taught to monitor skill use by self-evaluation – mark boxes on monitoring sheets; use cooperative progress charts for all
Adult mediation	Adult introduces and defines social communication skill; models examples using selected activity; role-plays with peers then focus child; prompts through peer first once per minute, then if unsuccessful, assists focus child; reinforces use of skill often at first, then fades, prompts, and reinforces
Videotape self- or peer modeling	Interactions are videotaped, then played back to discuss models of social skills, use of target skills, etc.
Plan for generalization	Train multiple peers; embed practice in natural inclusive settings; all staff aware of target skills; prompt and reinforce across the day; provide choices for activities; class-wide minisocial lessons, text cues, and visuals available across settings; coordinate home and community social activities

Peer Participation

Teachers recommend a group of 4–6 peers to participate in PMIs. To give ample time for social interactions and friendships to develop, the same groups of peers are involved in a PMI for the entire school year. After students begin to show increased interactions and engagement outside of PMI sessions, additional peers can be recruited. Parent consent may or may not be necessary based on classroom and school social curriculums.

Once a group of 4–6 peers have been recruited, an adult meets with them to explain the purpose of the groups, to review what it means to be a “buddy,” to find out preferred activities and popular games, and to talk about the social group schedule. This can be accomplished within one to two 30-min group sessions. Two peers are paired up with the focus student with ASD in small groups, and these pairings rotate across the week so each peer participates once per week. For younger children or children with more severe social needs, one peer can be paired up in a dyad with the focus child to decrease social demands and to increase opportunities for social skill practice.

Scheduling Social Groups

For direct teaching of social communication skills, groups meet 3–4 times per week for 20–30 min. A combination of structured practice and more naturalistic social opportunities is recommended. An adult sets up the social environment for success by including visual schedules, behavioral and reinforcement systems for increasing engagement, and preferred activities and games with simple rules. Opportunities to practice target social communication skills are embedded within less structured social times, when the context matches the skill (e.g., greeting and saying goodbye to peers, asking for items from peer at snack, asking peer for help in small group work). Multiple social opportunities exist within preschool centers, circle time, meal times, and dramatic play. As children advance through the grades and as the emphasis on academics increases, there is a need to become creative in providing social opportunities. Groups could

meet before or after school as part of school enrichment programs (e.g., breakfast club, games galore, drama club), at lunch (e.g., “lunch bunch”), at recess, or during the day when talking is allowed (small group work, art projects, etc.). The main idea is to provide numerous opportunities across the day to practice social skills taught in the small group format. This will greatly impact rate of learning and generalization of skill use.

Training Peers

Methods vary for training peers to be responsive conversational partners and to initiate and maintain interactions with children with ASD. In general, these methods are focused on teaching peers to model and prompt different social and language skills and provide corrective feedback and reinforcement to children with ASD. Peer training may take the form of meeting with peer buddies separately for group orientation, buddy training, and teaching specific facilitative social skills before joining a group with a child with autism. Alternatively, both peers and the child with autism can begin the groups together and be taught the same skills from the start of intervention. With this latter option, it is important for the adult to attend to the amount and level of language used when explaining the group goals, defining skills, etc. The child with autism may need a preferred reinforcer or behavior system to sit at the table with the group during the “teaching” time. Currently, the recommended method for training peers is to teach all children together and modify sessions accordingly to meet the needs of all children.

Two published curriculums for teaching preschoolers buddy skills include “Stay-Play-Talk” (English et al. 2005) and “Play Time/Social Time: Organizing your classroom to build interaction skills” (Odom and McConnell 1997). Examples of adult verbal prompts and social skills from Play Time/Social Time curriculum are listed in Table 3.

Table 4 lists examples of facilitative social communication skills and behavior substeps successfully taught to peers to be responsive conversational partners (Thiemann et al. 2012). Peers

Peer-Mediated Intervention, Table 3 Example prompts used in peer training from “play time/social time”

1. Sharing:
“___ wants to trade pictures with you. Please trade”
“___, give ___ a letter to put with the picture”
“___, ask ___ if she wants the picture”
2. Requesting to share:
“___, ask ___ to give you a letter. Point to the one you want”
“___, ask ___ if your puppet can share the word cards”
3. Play organizing:
“___, tell ___ to put his cat in the barn”
“___, tell ___ to put the word cat by the animal cat”
4. Agreeing:
“___, say, ‘Yes, my rat is thirsty’”
“___, make your cat follow ___’s cat”
“___, say, ‘Yes, I’ll help you say the words’”
5. Assisting and requesting assistance:
“___, help ___ sort the picture cards”
“___, ask ___ to help you match the letters to the pictures”
6. Persistence:
“___, show me ‘keep on trying’ with the word cards”
“___, show me ‘try another way’ with the picture matching”
“___, show ___ matching the cat to the word card, then ask again”

can also be taught to model and role-play target skills, use time delay prompts, and respond quickly and appropriately to their classmate with ASD.

Selecting Social Communication Goals

Young students with autism have a significantly restricted range or repertoire of social communication skills (e.g., language used to request objects or social routines, protest, greet, request information, and comment on personal or peer interests), and most demonstrate limited initiation skills. Evidence documenting characteristic social-communicative profiles of young students with PDD has distinguished them from children with other developmental disabilities and peers without disabilities (Wetherby and Prutting 1984). Typically developing preschool children exhibit 3–5 social initiations per minute during free play with peers, and this may vary up to 12 initiations. In comparison,

Peer-Mediated Intervention, Table 4 Examples of social communication skills to teach peers

<i>Skill #1: keep talking</i>
1. Listen to what a friend is saying
2. Show you are listening by saying, “sure” or nodding your head “yes”
3. Ask a question to find out more
<i>Skill #2: look, wait, and listen</i>
1. Look at friend who is talking
2. Show interest by sitting quietly
3. Hold up hands to show friend you are waiting
<i>Skill #3: answer questions</i>
1. Listen to friend’s question
2. Answer friend’s question
3. Tell friend if you do not understand
<i>Skill #4: start talking</i>
1. Choose a friend to talk to, say their name
2. Talk about what you see a friend doing
3. Tell a friend what you are doing
<i>Skill #5: say something nice</i>
1. Decide what to say something nice about
What your friend is making or doing
If a friend is winning or needs encouragement
What a friend is wearing
2. Give compliments in an honest, friendly way
3. Choose a good time to say something nice

students with autism primarily will initiate to adults and rarely to peers. Given the considerable limitations in social communication skills, and language spontaneity directed to peers, selecting and prioritizing communication goals is a challenging yet important first step.

Table 1 describes specific social communication skills and example text cues/scripts that have been successfully taught to preschool and school-age children within PMIs. One important consideration in selecting appropriate communication objectives is to choose behaviors that are effective in obtaining a positive response from peers or that enhance children’s responsiveness to their peers. For example, peers are more likely to respond to initiations of children with autism when their initiation attempt is combined with an attention-getting device (e.g., child looks at peer or says their name to get attention). Other strong predictors of successful communicative interactions are responding to what a peer just said and talking

about topics related to peer interests. Furthermore, children with autism may be more responsive to peer's verbal and nonverbal *requests* compared to other types of communication acts (English et al. 1997). Additional considerations in selecting appropriate target communication skills include (1) the child's language abilities in different social situations (e.g., performance vs. specific skill deficits), (2) behaviors that may impede positive peer interactions (e.g., physical aggression, being "bossy," talking too close or too quiet, or difficulty losing), (3) current IEP goals, and (4) family and teacher perceptions of social priorities.

Adult-Mediated Instruction

Each 30-min treatment session typically consists of 10 min of direct instruction, 15-min engagement in a social activity, and 5 min of adult feedback and reinforcement. Steps for direct teaching of social communication goals generally include:

1. Adult writes out group tasks on a visual agenda and reviews session goals.
2. Adult defines target social skill and substeps of skill (e.g., "Today we are going to learn how to say nice things to our friends. This means we can cheer for them or give compliments.").
3. Adult reads written-text cues that match target skill (inserted in standing clear 5 × 7 photo frame) and explains symbols or pictures that represent the communication skill (e.g., "Look, these children are cheering for their friend who won the game.").
4. Adult models target skill by reading the text cues, using parts/pieces of the upcoming activity or game.
5. Peers read cues and model/role-play target skill with each other.
6. Peers model/role-play the target skill with the child with ASD.
7. Adult teaches peer to prompt child to read/say the text cues of target skill.
8. Adult explains rules and expectations of social activity and shows children the reinforcement card that will be marked when they use the target skill. Visual cues of target skill are left on the table in child's direct line of view.
9. Adult sits back from the group and monitors child-peer communicative interactions during a 15-min activity. If no interactions occur, adult prompts peer once every 30 s to 1 min to prompt child with ASD to use the text cue card of the target skill. If peer is unsuccessful in gaining an appropriate response from the focus child, the adult intervenes and prompts accordingly.
10. Adult provides specific feedback on rate of skill use, shows performance of skill based on reinforcement card, and gives reinforcer as appropriate.

Efficacy Information

PMIs have long been recommended best practice for preschool children with autism based on intervention studies that span the last 40 years (McConnell 2002). Over the past 10–15 years, a growing number of studies have demonstrated positive outcomes for school-age children with ASD (Chan et al. 2009; National Standards Project 2009). Across these age groups, peer participation in social interventions should be considered recommended best practice for all individuals with autism. More evidence supporting implementation of peer training in natural school environments for older students is needed (Reichow and Volkmar 2010). Studies that are available for older students show that children with ASD and their peers can learn to communicate using functional or contextually appropriate language during age-appropriate games and activities, recess, lunch, and centers, for example. Communication improvements relate to greetings and gaining attention (e.g., saying hello, inviting others to play, saying child's name), commenting (e.g., "I have a match."; "You won."), requesting objects or actions (e.g., "Can I have the dice?"; "Roll the dice"), requesting information (e.g., "Who's winning?"; "Is it my turn?"), maintaining topics, and giving compliments (e.g., "Way to go!"; "Maybe next time") (Goldstein et al. 2007; Thiemann-Bourque 2010; Thiemann and Goldstein 2001; Thiemann-Bourque and Goldstein 2004; Thiemann and

Kamps 2008). Effective strategies used to teach communication skills within PMIs include video modeling, written-text cues, graphics, and other visual cues. Video modeling and other symbolic representations of social skills may be more effective when combined with other teaching techniques, as part of more comprehensive social programs.

Literature on social interventions for this population has emphasized the need for comprehensive programming that integrates or “layers” effective techniques in planning programs powerful enough to affect generalized and durable social outcomes (National Research Council 2001; Schwartz 2000). These model intervention “packages” often combine social-pragmatic and developmental approaches (e.g., targeting functional social-communicative skills in natural contexts) (Prizant and Wetherby 1998) with principles of contemporary behavioral interventions (e.g., multiple treatment components, systematic instruction of functional behaviors, access to preferred activities, and manipulation of ecological variables) (Horner et al. 1990). Schwartz discussed a promising intervention model that focuses on adult mediation, child’s skill repertoire, the social environment, and peer skills, supports, and expectations to guide children’s social relationships in natural settings. Recent PMI studies incorporating similar components of this model have reported the following benefits to students with ASD: (a) increased social initiations, (b) improved functional expressive language, (c) decreased unintelligible utterances, (d) use of new skills across novel and varied settings and social partners, (e) fewer inappropriate social utterances and behaviors, (f) improved friendship ratings, and (g) enhanced overall quality of interactions.

Evidence supporting PMIs is based primarily on multiple-baseline and alternating treatment experimental designs. There are over 50 single-subject experimental design studies, most of which contribute to evidence of robust effects of social skill interventions for young children with autism. Much has been learned from this literature. The focus is now shifting toward larger randomized control studies that compare PMIs with “business as usual” or traditional

interventions. Furthermore, there are currently a number of therapy resources that promote the use of pictures, symbols with text cues, and other illustrations of social interactions (e.g., Baker 2003; Kelly 1996); additional studies are necessary to document the effectiveness of these approaches on social interactions. These studies will be important to increase understanding of what components of comprehensive PMIs are critical to impact more lasting social changes and how to ensure feasibility of implementation for school staff.

Outcome Measurement

Reports of social outcomes have historically focused on measuring changes in the duration of an interaction, proximity to peers, and changes in rates of social initiations. There has been a growing emphasis on the need to measure multiple social outcomes that include social communication competence, social acceptance, and friendship development. Outcome measures have advanced to include verbal social communication (e.g., requests, comments, offers to share), nonverbal communication (e.g., facial expressions, body language), prelinguistic communication (e.g., gestures, eye gaze, joint attention), and conversational skills (e.g., topic maintenance). Measuring skill used within contexts that involve new (untrained) peers, novel activities, and games and that took place in nontreatment settings would indicate generalization of treatment gains. If generalization of skills is not observed, students need continued adult prompts and peer supports embedded within these novel, naturalistic settings.

A true measure of social success is the ability of individuals with and without ASD to engage in positive and successful interactions leading toward development of friendships. Haring and Breen (1992) adeptly provided the groundwork to measure this outcome by asking questions about friendship supports and relationships for junior high students (with autism and DD) following participation in peer networks. Measures included peer reports of interactions with the focus students based on invitations to

extracurricular activities and interactions in the hallway, locker areas, cafeteria, and school field. Children perceived as being more socially competent are more likely to be accepted by peers and to be chosen as friends. These outcomes can be measured by asking peers to complete friendship or acceptance questionnaires at the beginning and end of the school year. For younger children, one way to assess acceptance is to ask them to place a photo of a “buddy” in their class that they would like to take on a train ride at the zoo (with connected paper train cars). For older students, rating scales with smiley faces can be used to assess acceptance with questions such as “Would you like to sit beside _____ at lunch time?” or “Do you play with _____ on the playground?” or “Would you like to be partners with _____ to do an art project?” etc. Knowledge of how student’s social engagement and acceptance are developing outside of the treatment setting is critical to guide intervention efforts to enhance long-term friendships.

Qualifications of Treatment Providers

The ASHA (2006) published guidelines for speech-language pathologists (SLPs) working with individuals with ASD. These guidelines stress the critical role of SLPs in supporting the child with ASD and the communication partner (e.g., peers). Effective PMIs require strong collaborative relationships between SLPs and members of school support teams. In-service training and workshops should be provided to SLPs and other service providers such as school psychologists, counselors, paraprofessionals, and special education teachers. Regular education teachers are not typically involved in direct peer instruction, given that they have a classroom of students to manage; however, they can be instrumental in capitalizing on classroom or playground social opportunities to reinforce target social communication goals in inclusive settings. Training and involvement of multiple treatment providers can lead to improved generalized social outcomes if everyone is aware of and working on the same peer-related social communication goals.

PEERS

Elizabeth Laugeson

UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, USA

Definition

The Program for the Education and Enrichment of Relational Skills (PEERS®), developed at the University of California, Los Angeles (UCLA), by Drs. Elizabeth Laugeson and Fred Frankel, is a caregiver-assisted group treatment intervention aimed at improving social skills among youth with autism spectrum disorder (ASD) and other social challenges. This international program, which is used in over 90 countries and has been translated into over a dozen languages, is one of the only evidence-based social skills interventions for youth with ASD. The group-based intervention has been developed and tested for transitional youth from adolescence to early adulthood and has generated four published evidence-based treatment manuals for practitioners and educators.

Social Skills for Teenagers with Developmental and Autism Spectrum Disorders: The PEERS® Treatment Manual (Laugeson and Frankel 2010), which is a 14-week parent-assisted intervention for adolescents with ASD, was the first published manual to highlight this empirically supported program. This manual has also been translated into Korean (Laugeson and Frankel 2014), following a cross-cultural validation trial. *The PEERS® Curriculum for School-Based Professionals: Social Skills Training for Adolescents with Autism Spectrum Disorder* (Laugeson 2014) extends the PEERS® intervention into the school setting using a teacher-facilitated model with a 16-week daily lesson format. *PEERS® for Young Adults: Social Skills Training for Adults with Autism Spectrum Disorder and Other Social Challenges* (Laugeson and Frankel 2017) is the most recent publication. Geared for young adults with ASD, this caregiver-assisted intervention includes 16 weekly group treatment sessions to improve social functioning.

The PEERS[®] curriculum teaches ecologically valid rules and steps of social etiquette in a simple way for teens and young adults with ASD to understand social contexts. While typically developing children and adolescents often learn basic social rules through observation of peer behavior and/or specific instruction from parents, understanding and utilizing social etiquette is often more difficult for adolescents and young adults with ASD. Instead, teaching social skills through the identification of concrete rules and steps of social etiquette, demonstrating these social behaviors through role-playing examples, and providing behavioral rehearsal exercises with performance feedback are the essential ingredients to improving social functioning using the PEERS[®] method. Moreover, repetition of rehearsal through homework and supervised implementation of the skills through parent, caregiver, and/or teacher coaching is also critical to the development of social skills among adolescents and young adults using the PEERS[®] method.

Historical Background

Numerous studies have shown that social skills are an important factor in long-term adjustment for individuals with ASD. Consequently, social skills training is a well-documented intervention strategy for children on the spectrum, having the potential to greatly impact quality of life and increase independence. Studies investigating the effectiveness of social skills training for individuals with ASD indicate that intervention during childhood and adolescence is critical. However, to date there are very few evidence-based treatments focused on improving social skills for adolescents or young adults with autism. Meta-analyses of the literature suggest that social skills training does not produce large, socially important, long-term, or generalized changes in social competence among individuals with ASD (Reichow and Volkmar 2010; Rao et al. 2008; Reichow et al. 2013). These limitations are what lead to the development of PEERS[®].

Originally developed in 2004 at UCLA by Drs. Elizabeth Laugeson and Fred Frankel, PEERS[®] is

one of the only evidence-based social skills interventions for adolescents and adults with ASD. Numerous scientific papers have highlighted the efficacy and effectiveness of the program for adolescents with ASD (Laugeson et al. 2009, 2012, 2014; Van Hecke et al. 2015; Karst et al. 2015; Schohl et al. 2013; Yoo et al. 2014), adults with ASD (Gantman et al. 2012; Laugeson et al. 2015), and even youth with other social challenges like attention-deficit/hyperactivity disorder (ADHD; Gardner et al. 2015). Most of these studies have utilized randomized controlled trial designs, which is widely considered the gold standard for assessing treatment outcome.

Rationale or Underlying Theory

Utilizing the principles of cognitive behavioral therapy (CBT), PEERS[®] applies the teaching methods of didactic instruction/psychoeducation, role-play demonstration, cognitive strategies, behavioral rehearsal, performance feedback, homework assignment and review, and parent involvement within a small group treatment format (e.g., eight to ten group members). The general effectiveness of the PEERS[®] method might be credited to the use of evidence-based methods of treatment delivery, borrowed from the CBT approach, in combination with the inclusion of parents and/or other caregivers in treatment, who ensure the generalizability and durability of treatment gains in the months and years following intervention (Mandelberg et al. 2014).

Goals and Objectives

PEERS[®] focuses on teaching social skills related to making and keeping friends, as well as managing conflict and rejection. Didactic content for developing romantic relationships is also included in the young adult curriculum. Lessons include starting and maintaining conversations, finding a source of friends, electronic forms of communication, using humor appropriately, entering and exiting conversations, good sportsmanship (adolescents only), organizing and having successful get-togethers,

dating etiquette (adults only), managing disagreements, changing a bad reputation (adolescent only), and handling direct and indirect bullying and other forms of rejection (teasing, physical bullying, cyberbullying, and rumors/gossip).

Rules and steps of social behavior are developed from research evidence regarding (1) the common social errors often committed by those with ASD, (2) the core social skills needed to make and keep friends and develop romantic relationships, and (3) the ecologically valid ways in which socially accepted individuals handle peer conflict and rejection.

The PEERS[®] manuals are meant to be used as complete programs in their entirety. Lessons are intended to be delivered in the order they are presented as each skill builds upon the last. Didactic lessons are based upon ecologically valid social skills known to be used by socially successful people. The techniques used, such as role-play demonstrations, behavioral rehearsal exercises, and homework assignments, have been shown to improve social skills outcomes through research.

Treatment Participants

The PEERS[®] intervention is intended for socially motivated adolescents and adults with ASD without significant intellectual disabilities. The treatment was originally developed as a parent-assisted intervention focusing on teens in middle school and high school who were having difficulty making and keeping friends. The program has been field tested extensively with teens and young adults with ASD and to a lesser extent with adolescents diagnosed with intellectual disabilities and fetal alcohol spectrum disorders, as well as adolescents and adults with attention deficit hyperactivity disorder (ADHD). PEERS[®] is also used clinically with teens and young adults with depression, anxiety, and other social challenges.

Treatment Procedures

Research assessing psychosocial functioning among adolescents and adults with ASD has

found that these individuals often have extensive need for help from their families and/or society. Studies report that very few adults on the spectrum live in typical psychosocial conditions. Instead, they most often live with parents or alone, seldom have relationships with partners, and are often without employment of any kind. These outcomes suggest the need for parent, caregiver, and/or teacher involvement in treatment to improve social functioning for transitional youth with ASD.

One method utilized by PEERS[®] for teaching social skills to youth with ASD includes parent assistance. In this case, parents are included in the treatment, attending separate but concurrent weekly group sessions in which they are taught to be social coaches to their teens. Meanwhile, adolescents are given instruction on the rules and steps of social etiquette related to making and keeping friends while given opportunities to practice newly learned skills.

Another method used by PEERS[®] for teaching social skills to youth with ASD involves teacher facilitation. In this case, social skills are taught in the classroom, much in the way one might teach math or science. Lessons are broken down using concrete rules and steps of social etiquette, taught by teachers, demonstrated by teaching staff, and practiced daily by students in the classroom.

In addition to parent-assisted and teacher-facilitated social skills training, PEERS[®] also utilizes a caregiver-assisted model in working with young adults with ASD. In this case, social coaching is provided by caregivers close to the young adults, such as parents, adult siblings, peer mentors, job coaches, life coaches, or other family members.

In the parent-/caregiver-assisted interventions, treatment consists of 14–16 weekly 90-minute group sessions. Adolescents, young adults, and their caregivers attend separate concurrent sessions. Didactic instruction is provided using concrete rules and steps of ecologically valid social behavior. Within the adolescent and young adult groups, social rules and steps are presented using a Socratic method of questioning, intending to promote and enhance participation in the lesson. Role-play demonstrations of targeted behaviors

are also used to model appropriate and inappropriate examples of the rules and steps. In order to enhance social cognition, role-play demonstrations are followed by perspective-taking questions in which participants are asked to take on the perspective of the receiver of the appropriate or inappropriate social behavior. Structured practice follows each lesson through a behavioral rehearsal exercise in which young adults practice the appropriate newly learned skills while receiving performance feedback through social coaching by the treatment team. Socialization homework assignments are given for each of the targeted social skills to support generalization of skills outside of the treatment setting. Homework review takes place in the following week, with sufficient time to troubleshoot any issues that may have arisen and to individualize the treatment to participants as needed.

Within the parent and caregiver groups, homework review comprises the majority of the session in order to include specific instructions on how to provide assistance with social coaching to adolescents and young adults during weekly homework assignments. Didactic instruction follows homework review in the parent and caregiver groups through the distribution and review of social coaching handouts, which provide an outline of the rules and steps of the targeted social skills, along with a comprehensive description of the upcoming homework assignments. Within the didactic lesson, parents and caregivers are also given specific instruction on how to provide social coaching to adolescents and young adults outside of the treatment setting. These strategies are tailored to the specific needs of each individual as necessary. The use of parent/caregiver-assistance in treatment is utilized in order to enhance generalization of social skills through in vivo social coaching in natural social settings (when appropriate) and to increase homework compliance and practicing of newly learned skills. Parents and caregivers are also expected to enhance the durability of treatment gains through continual social coaching even after the PEERS[®] intervention had ended.

Within the teacher-facilitated intervention, the PEERS[®] curriculum consists of daily 30–50 min

lessons, delivered in the school setting 5 days per week over the course of 16 weeks. Key elements of the intervention are also taught using evidence-based methods of instruction provided by teaching staff. Didactic instructions about simple rules and steps of social etiquette related to making and keeping friends and handling peer conflict and peer rejection are provided using ecologically valid social skills based on the norms established by socially accepted teens. Didactic lessons are followed by role-play demonstrations of targeted skills by teaching staff. Students practice newly learned skills in the classroom while receiving performance feedback from teaching staff during behavioral rehearsal exercises. Socialization homework assignments are given to generalize skills outside of the school setting and are reviewed by students and teaching staff at the beginning of each week. Parents also receive psychoeducation about skills needed for teens to develop and maintain friendships via weekly parent handouts, which are generally sent home through classroom communication logs or via email. Through these handouts, parents are provided instruction about how to help their teen make and keep friends and assist their teen in expanding his/her social network through the enrollment in extracurricular activities.

Efficacy Information

While social skills training is an important treatment priority for many young adults with ASD and other social challenges, much of the research literature in this area has focused on interventions with children. Very few social skills intervention studies have been devoted to investigating the efficacy and effectiveness of social skills training for adolescents or young adults. Moreover, few social skills programs focus on the development and maintenance of friendships and romantic relationships. Even among the social skills intervention studies conducted with the ASD population, most have not been formally tested in terms of improving social competence or the development of close friendships, nor have they assessed the benefit of including caregivers in training in order

to promote social functioning. The lack of evidence-based social skills instruction to improve social competence and promote the formation of friendships for young adults with ASD and other social challenges is what inspired the development of PEERS®.

Most of the research examining the efficacy of PEERS® has been conducted at the UCLA Semel Institute for Neuroscience and Human Behavior, under the direction of Dr. Elizabeth Laugeson, the co-developer of the intervention. Multiple independent replication trials have also been conducted at Marquette University, under the direction of Dr. Amy Van Hecke, and several cross-cultural validation trials of PEERS® have also taken place outside of North America, with the first cross-cultural validation study lead by Dr. Heejeong Yoo at Seoul National University in South Korea. Across all of these trials, most of which have included randomized controlled trial designs, the treatment effects have been strikingly similar.

Results from the aforementioned research labs demonstrate that PEERS® is efficacious in improving social skills for adolescents and young adults with ASD without intellectual disability (Laugeson et al. 2009, 2012, 2014, 2015; Van Hecke et al. 2015; Karst et al. 2015; Schohl et al. 2013; Yoo et al. 2014; Gantman et al. 2012). Research findings primarily come from parents, teachers, and youth, using standardized measures of social functioning. Improvements in social functioning following PEERS typically include:

- Improved overall *social skills* in the areas of:
 - Cooperation
 - Assertion
 - Responsibility
- Decreased *problematic social behaviors* in the areas of:
 - Self-control
 - Externalizing behavior
- Improved *social responsiveness* in the areas of:
 - Social communication
 - Social awareness
 - Social motivation
 - Social cognition
 - Decreased autistic symptoms

- Decreased social anxiety
- Increased frequency of peer interactions and get-togethers
- Decreased loneliness
- Improved empathy
- Improved friendship quality
- Improved knowledge of adolescent or young adult social skills

Unlike most social skills interventions cited in the research literature, extensive follow-up research has been conducted with PEERS®, investigating the sustainability of these improvements over time (Mandelberg et al. 2014). A long-term follow-up study conducted at UCLA with families 1–5 years after receiving the PEERS® treatment revealed that improvements in social skills, social responsiveness, frequency of peer interactions, and social skills knowledge were maintained over time and in some cases improved even further. These findings are encouraging when you consider that the social trajectory for many young people with ASD sadly tends to worsen with age and upon entering adulthood.

Also noteworthy is that the abovementioned studies not only comprise the largest number of participants reported in the social skills treatment literature for older adolescents and young adults with ASD, but the improvements are far greater than what is typically reported in the autism research literature. Most social skills treatment studies for young people with ASD tend to show minimal or modest improvements, often with a very small group of people, and with improvements rarely sustained or reported over time. Conversely, research using the PEERS® model has shown much greater improvements in social skills among larger groups of people, with improvements generally maintained over time and improved even further in some cases.

Outcome Measurement

Tracking progress is an essential part of determining whether treatment is working. Below is a list of the tests used in published scientific studies

with PEERS[®]. Standardized assessments of social functioning are included. These measures are widely available and have shown substantial change following the program.

Test of Adolescent/Young Adult Social Skills Knowledge (TASSK/TYASSK; Laugeson and Frankel 2010; Laugeson 2014; Laugeson 2017). The TASSK and TYASSK are 30-item criterion-referenced tests developed for PEERS[®] to assess knowledge about the specific social skills taught during the intervention. Items are derived from key elements from each of the 15 didactic lessons. Adolescents (TASSK) and young adults (TYASSK) are presented with sentence stems and asked to choose the best option from two possible answers. Scores range from 0 to 30, with higher scores reflecting greater knowledge of adult social skills. Previous research using the TASSK/TYASSK to track treatment outcome in PEERS[®] generally yields a 6–8 point raw score improvement from pre- to posttest.

Quality of Socialization Questionnaire (QSQ; Laugeson and Frankel 2010; Laugeson 2014; Laugeson 2017). The QSQ is independently administered to adolescents, young adults, and caregivers to assess the frequency of get-togethers with peers in the previous month and the level of conflict during get-togethers with peers. Previous research using the QSQ to track treatment outcome in PEERS[®] generally reveals two to four additional get-togethers per month from pre- to posttest.

Social Responsiveness Scale – Second Edition (SRS-2; Constantino 2012). The SRS-2 consists of 65 items assessing the presence and severity of social deficits (i.e., social awareness, social cognition, social communication, social motivation, and restricted interests and repetitive behaviors) associated with ASD as they occur in natural social settings. The SRS-2 can be completed by parents, teachers, and other caregivers. Previous research using the SRS-2 to track treatment outcome in PEERS[®] generally yields a full standard deviation improvement (10 T-score points) from pre- to posttest.

Social Skills Improvement System (SSIS; Gresham and Elliott 2008). The SSIS is a standardized, 75-item measure that assesses social skills (communication, cooperation, assertion,

responsibility, empathy, engagement, self-control) and problem behaviors (externalizing and internalizing behaviors, bullying, hyperactivity and inattention, autism spectrum disorder-related behaviors). Although developed for youth between 13 and 18 years, the SSIS has also been used successfully with young adults to track change in social skills following PEERS[®] (Gantman et al. 2012; Laugeson et al. 2015). Using a four-point rating system, parents, teachers, and caregivers rate the frequency and relative importance of various social skills and problem behaviors. Previous research using the SSIS to track treatment outcome in PEERS[®] typically reveals nearly a standard deviation improvement (10 standard score points) from pre- to posttest.

Qualifications of Treatment Providers

Clinicians need not have much experience running social skills groups in order to use the manual effectively, but they should have background knowledge in working with adolescents or young adults with ASD or other social challenges and their caregivers. Since anyone is able to purchase the PEERS[®] manuals commercially, the program is used extensively throughout the world by practitioners and educators with very little training in social skills treatment. For those wishing to obtain more extensive training on the implementation of this intervention, PEERS[®] Certified Training Seminars for qualified medical/mental health professionals and educators are regularly conducted at and outside of UCLA by the program developer, but such training is not required to run a PEERS[®] program.

Peers, Exposure to

Erin Rotheram-Fuller¹ and Mina Kim²

¹School Psychology, Department of Psychological Studies in Education, College of Education Temple University, Philadelphia, PA, USA

²College of Education Temple University, Philadelphia, PA, USA

Definition

Exposure to typically developing peers is often used as an intervention to improve the socialization

of children with autism spectrum disorders (ASD). Exposure to typical peer models provides examples of age-appropriate social behavior as well as opportunities to engage in those age-appropriate activities. Exposure to peers is also used to try to improve peer acceptance of children with ASD and appreciation of differences. Interventions utilizing exposure to typically developing peers often occur in the school setting, in inclusive classrooms or environments. Peers may be trained or untrained, and adults may or may not facilitate interactions between the peers and child with ASD. However, there is an overall emphasis to reduce adult intrusion and instead arrange the physical space to increase the likelihood of interactive play (Bellini et al. 2007b).

Historical Background

Peer relationships are considered to be a crucial factor for healthy academic and social development (Birch and Ladd 1998). There has been an increasing push to include children with ASD into regular education classrooms (Falvey 1995; Guralnick 1990; Kasari et al. 1999; Villa and Thousand 1995). One goal of inclusion is to increase the exposure of children with ASD to typically developing peers, and ultimately develop social relationships (Gallagher et al. 2000). In autism-specific classrooms, children are often surrounded by children with similar social challenges to themselves and do not have the same opportunities to observe or practice peer-peer positive social interactions. Children with ASD have difficulties in social interaction as a hallmark of the disorder (American Psychiatric Association [APA] 2000). These social deficits can affect children with ASD's theory of mind (the ability to take another person's perspective; Peterson et al. 2007), communication skills (both verbal and nonverbal), interpretation skills of other's behavior, as well as their ability to stay on socially relevant topics (Jackson et al. 2003; Palmen et al. 2008). Children with ASD seem to lack two of the most important qualities for successful peer relationships: the ability to relate

positively and reciprocally to peers and the ability to easily adapt to changes in social situations (Schopler and Mesibov 1986). Complex communication skills require a high level of sensitivity in order to recognize social cues, and children with ASD often lack the social skills required to interpret those cues and connect with others (Chawarska et al. 2003). An inability to effectively communicate can severely impede the development and maintenance of peer relationships, when children cannot accurately understand one another, and having two children with social difficulties trying to interact only increases this challenge. By exposing the child with ASD to typically developing peers, there is an increased opportunity for the peer to adapt to the child with ASD's unique communication style and interact successfully. Children with ASD also do not attend to social cues, such as eye gaze, similar to their typical peers, and appear to process these visual cues differently (Chawarska et al. 2003). Other social challenges of children with ASD include inappropriate behaviors, such as failing to initiate conversations and/or respond to others, difficulties in turn-taking, and perseveration (APA 2000). In addition, children with ASD may respond to failures in communication by getting frustrated and reverting to earlier forms of communication, such as crying and throwing tantrums, instead of working to repair the miscommunication (Koegel et al. 2001). Children with ASD may also have disruptive, aggressive, age-inappropriate, or repetitive behaviors, such as hand-flapping, echolalia, and prosody of speech (Downs and Smith 2004; McEvoy et al. 1993). As a result of these challenges, many children with ASD have difficulty developing and maintaining peer relationships. Exposure to typically developing peers has the goal of improving social engagement and addressing some of these core deficits.

Rationale or Underlying Theory

Children with disabilities are often stigmatized, and the negative effects of stigmatization can be carried into adulthood (Koegel et al. 2001). Similarly, children who demonstrate difficulties

forming peer relationships in their earlier years have a higher incidence of emotional maladjustment in later years (Schopler and Mesibov 1986). Children with ASD do not engage in spontaneous play with other children and often fail to develop meaningful friendships (Koegel et al. 2001). However, positive peer relationships are related to improved academic performance, physical and behavioral outcomes, and increased feelings of companionship, self-worth, and self-esteem and may serve as a protective factor (Brendgen et al. 2005; Farmer et al. 2008; Gest et al. 2001). Thus, promoting the development of peer relationships is crucial for the social and emotional development of children with ASD.

Exposure to typically developing peers offers a unique method of social training for the child with ASD. Peers are of similar age to the child with ASD and thus can become highly salient for the child with ASD to observe and try to emulate (as opposed to exposure to adults). Peers can also provide a desired acceptance and social praise for the child with ASD. Some children with ASD have been shown to be aware of their social status within the classroom and have shown increased ratings of loneliness as a result of that understanding (Bauminger and Kasari 2000). Using peers to teach children with ASD how to appropriately interact socially may provide some inherent social rewards and reinforcement for the child with ASD to not only increase the desired social behavior but also increase their motivation to continue to emulate and seek out social interactions with their peers. Often when trying to shape the behavior of a child with ASD, artificial reinforcers are used (e.g., stickers, tokens, time on the computer) to reward the child for desired behavior. However, when peers respond positively to the child with ASD for exhibiting appropriate social behavior, that natural reward may be a more powerful reinforcer and motivator to increase the desired behavior than artificial tokens. Even using artificial rewards for appropriate behavior in real-life social experiences (e.g., rewarded for play on the playground) is more likely to achieve real and longer-lasting results than rewards for appropriate role-play in artificial clinical settings.

Goals and Objectives

Children with ASD are exposed to typical peers with the goal of increasing interaction and appropriate social skills as well as exposing the child to more age-appropriate behavior. There is a hope that exposure to typical peer models will result in a corresponding increase in the social skills and generalizability of those skills in the natural setting by children with ASD. Since play is important in forming a basis for peer relationships, many interventions focus on teaching and promoting specific play skills (Schopler and Mesibov 1986). Targeting specific behaviors, such as decreasing stereotypic behaviors and tantrums and increasing play and cooperation, may also play an important role in long-term development and contribute to subjective observers' improved global impressions of the child with ASD (Koegel et al. 2001).

Exposure to typically developing peers also provides naturalistic rewards for age-appropriate social behavior as well as increased opportunities for social communication, play, and social engagement. Some of the goals of exposure for peers to children with ASD are to increase their acceptance of children with special needs as well as increasing their understanding, empathy, and adaptive skills.

Treatment Participants

Treatment involving exposure to peers has focused mainly on children with ASD under the age of 15 years and their typically developing, preferably same-aged peers. Only a few studies have examined older students (Harris 1998). Typically developing peers can be selected based on classroom proximity or on specific qualities of the peer (e.g., empathetic, having good social skills, or of average social acceptance themselves; Kasari et al. 2010). Adults, such as parents and teachers, are also used to teach typical peers how to appropriately model social skills to children with ASD. However, the involvement of adults is often for peer training and observation purposes only and is otherwise minimal (Bellini et al. 2007b).

Treatment Procedures

Studies looking at exposure to peers can take many forms. Inclusion models often use classroom proximity alone to expose children with ASD to typically developing peer models. Classroom proximity may also be used with school- or class-wide training in appropriate positive social behavior (e.g., school-wide rules such as “everyone is allowed to play”). Targeted training of peers has also been used to facilitate interaction with children with ASD, where peers are specifically trained in social engagement techniques. Children with ASD can also be trained in specific social skills prior to social exposure to peers to increase the likelihood of appropriate social interaction. Finally, adults can serve as facilitators to increase the opportunities for interaction between the peers and the child with ASD (Luiselli et al. 2008). Procedures used in training of the child with ASD or typically developing peers can range from modeling, role-play, discrete trial training, social stories, and pivotal response training to self-management training or assigning peer buddies (Ferraioli and Harris 2010; Luiselli et al. 2008). Peers play a variety of roles, acting as tutors, models, partners, and trainers (Luiselli et al.).

Most of the interventions promoting exposure to peers have utilized single-subject designs, with a variation of multiple-baseline or probe design being the most common (Bellini et al. 2007a). There is an overall lack of consistency in interventions, with the number of sessions ranging from 8 to 73 sessions and treatment ranging from 2.5 to 28 h and 10–210 days (Bellini et al. 2007a). The interventions have been conducted in schools, in classrooms, and in common areas, such as playgrounds and cafeterias, the child’s home, and the community.

Peer exposure training is also used to teach a variety of social skills and behaviors. Much of the research literature has focused on verbal communication, such as initiation and responses, and social behaviors, such as sharing, helping, and showing affection (Bellini et al. 2007b; Rotheram-Fuller and Kasari 2010). There are two main categories of behaviors targeted by peer-mediated interventions: specific, well-defined

skills or behaviors or more diffuse socialization ability without a focus on particular skills (Rotheram-Fuller and Kasari 2010). Some of the specific behaviors that have been studied are smiling and laughing with peers, entering ongoing peer activities, and giving compliments and praise (Schopler and Mesibov 1986). The more general approach has focused on promoting overall social interaction skills in a less specified manner and may utilize social skills or friendship groups to increase participation in peer activities or cooperative play or measure complex concepts, such as friendship quality (Rotheram-Fuller and Kasari 2010; Schopler and Mesibov 1986). According to Koegel et al. (2001), intervention focus should shift away from studying specific targeted behaviors to a more global approach that focuses on results, and emphasis should be placed on identifying the behaviors that will impact other behaviors, rather than treating each individual behavior independently.

Efficacy Information

There is mixed evidence for the efficacy of exposure to peers as an intervention technique. Exposure to peers has been shown to help children with ASD form successful relationships with typically developing peers and to improve social skills (Carr and Darcy 1990; Garfinkle and Schwartz 2002; Ryndak et al. 1995). Exposure to multiple peers has also been shown to increase the generalizability and maintenance effects of the social skills treatments (Bellini et al. 2007b).

Exposure to peers may also indirectly improve the social skills of the typical peer in addition to the social skills of the child with ASD. Typical peers may become more sympathetic and empathetic, show increased tolerance and social awareness, and learn how to reduce the stress of interacting with the child with ASD (Koegel et al. 2001).

However, other peer-mediated interventions have had limited success due to the difficulty of teaching children with ASD how to spontaneously initiate social interactions (Harris 1998). Much of the training has been focused on

initiating social interactions; however, children with ASD do not easily transform initiations into extended conversations (Rotheram-Fuller and Kasari 2010). Another challenge in evaluating the efficacy of peer-mediated interventions is the lack of consistency of interventions and their outcome measures. Many studies collect outcomes measuring the specific skills that were targeted in the interventions, which make it difficult to determine if improvements have been made in other areas, such as the child's global social functioning.

Traditional programs of simple exposure through proximity have been minimally effective in teaching social skills to children with ASD; however, programs that target specific social skills have been found to be more effective than programs focusing on global social functioning (Bellini et al. 2007b).

Peer interactions with children with ASD occur more frequently in inclusive settings; although, research on inclusion suggests that inclusion and peer exposure are not sufficient for teaching children with ASD the more subtle social skills, such as keeping up with topic changes in conversation (Wagner 1999). Children in inclusive classrooms are simply placed in proximity to the other children in the class, without scaffolding on how to appropriately interact. While typically developing peers naturally tend to interact with others similar to themselves (Kemple 2004), this leaves children with ASD within that classroom at a disadvantage. It is often necessary for adults to facilitate social interaction in order for inclusion to be truly successful (Kemple 2004).

In a recent study comparing the efficacy of training the child with ASD compared to training typical peers to engage with the child with ASD, it was found that training peers can be more successful at improving the social involvement of the child with ASD into the regular classroom (Kasari et al. 2010). Peer interventions have been shown to be particularly effective in generalizing the skills across settings and people (Bellini et al. 2007b; Luiselli et al. 2008) and also have been found to be maintained over time (Mastergeorge et al. 2003). Parents and teachers have also reported increases in language and appropriate play skills and decreases in solitary play

(Wagner 1999). However, it is recommended that interventions should be implemented more frequently and intensely than is typical (Bellini et al. 2007b). More information is needed, however, to identify which interventions work best with which children and who might benefit most from inclusion practices.

Outcome Measurement

The outcome measures used across studies of exposure to peers vary considerably. There is no standard measurement to determine success of the intervention, and studies utilize both specific and global measures. The majority of outcomes could be categorized into two main areas: observations of specific skills to gauge improvement and standardized measures (including teacher, parent, child, or peer reports; Bellini et al. 2007a; White et al. 2007). Given the spectrum nature of ASD, there are a broad set of target behaviors that are examined to determine social success. While an intervention targeting initiations must record initiations as an outcome, it is difficult to compare such an intervention to one that focuses on a different specific skill, such as increasing the number of friendships for the child. The specific skills that have been measured include social initiations, greetings, and responses, while the more global social skills include play skills, problem-solving skills, and exercising self-control (Bellini et al. 2007a; Rao et al. 2008).

Qualifications of Treatment Providers

No specialized training has been identified as necessary for providing treatment in peer exposure interventions. Parents, teachers, care providers, and siblings, as well as peers are typically used to provide training to the child with ASD (or typically developing peers). In the most basic form of exposure (proximity), children with ASD are exposed to typical peers in a naturalistic setting with no adult intervention or prior training. However, across studies, those that used more facilitation from adults or training of peers

prior to exposure appear more effective at improving the social engagement of the child with ASD. Thus, training on social skills curriculums or specific intervention methods (pivotal response training, discrete trial training, etc.) is recommended to increase the efficacy of this approach. Training for treatment providers typically involves ensuring that data is collected correctly; additional training should be efficient (quick, minimal resources), effective (produce the desired outcomes), and acceptable (address needs and promote generalization of skills; Luiselli et al. 2008). Similarly for teachers, no intervention is expected as part of an inclusion classroom; however, providing guidance or activities with the class can increase or facilitate social engagement among all students, including the child with ASD.
